ZUSAMMENFASSUNG

Hintergrund Der hochintensive fokussierte Ultraschall (HIFU) ermöglicht das nichtinvasive Erhitzen tief gelegener Gewebsschichten. Die MRT-geführte HIFU-Behandlung (MR-HIFU) erlaubt die präzise Therapieplanung sowie MR-basierte Temperaturmessungen im Gewebe, wodurch eine genau definierte thermale Dosis appliziert werden kann.

Methoden Publikationen zu MR-HIFU wurden studiert und in diesem Review zusammengefasst. Hierbei wurde die Literatur auf onkologische Applikationen beschränkt.

Ergebnisse Neueste Studien zur MR-HIFU-Therapie des Prostatakarzinoms bestätigten diese als sichere und patientenfreundliche Methode. Zur MR-HIFU-Therapie des Mammakarzinoms und Tumorerkrankungen der abdominalen Organe wurden bisher Machbarkeitsstudien publiziert.

Zusammenfassung MR-HIFU wird derzeit für die Thermoablation von malignem Gewebe bei verschiedenen Krebsentitäten untersucht. Die sowohl transrektale als auch transurethrale Ablation des Prostatakarzinoms mittels MR-HIFU erwies sich als patientenfreundlich und sichere Alternative mit geringen Komplikationen im Vergleich zu anderen lokalen Therapieoptionen.

Kernaussagen:

- Die MR-Steuerung ermöglicht Therapieplanung auf MR-Bildern, nichtinvasive Temperaturmessungen in Echtzeit sowie postinterventionelle Therapiekontrolle.
- Spezielle HIFU-Transducer und Technologien zur Therapie vom z. B. Prostata- und Mammakarzinom oder malignen Erkrankungen der Abdomen-Organen sind vorhanden.

ABSTRACT

Background High-intensity focused ultrasound (HIFU) allows noninvasive heating of deep-seated tissues. Guidance under magnetic resonance imaging (MR-HIFU) offers spatial targeting based on anatomical MR images as well as MR-based near-real-time temperature maps. Temperature feedback allows delivery of a well-defined thermal dose enabling new applications such as the ablation of malignant tissue.

Methods Peer-reviewed publications on MR-HIFU were studied and are summarized in this review. Literature was restricted to applications in oncology.

Results Several MR-HIFU-based applications for the treatment of malignant diseases are currently part of clinical trials or translational research. Recent trials regarding the treatment of prostate cancer with MR-HIFU have already shown this to be a safe and patient-friendly method. For the treatment of breast cancer and malignancies within abdominal organs, MR-HIFU has been applied so far only in proof of concept studies.

Conclusion MR-HIFU is currently being investigated for the ablative treatment of malignant tissue in a variety of oncological applications. For example, the transrectal as well as transurethral ablation of prostate cancer using MR-HIFU was shown to be a patient-friendly, safe alternative to other local treatment options with low side effects.

Key points:

- MR guidance offers high soft tissue contrast for treatment planning, near-real-time temperature monitoring, and post-interventional therapy evaluation.
- Special HIFU transducers and technological solutions are available for the treatment of e. g. prostate cancer, breast cancer or abdominal malignancies.

Introduction

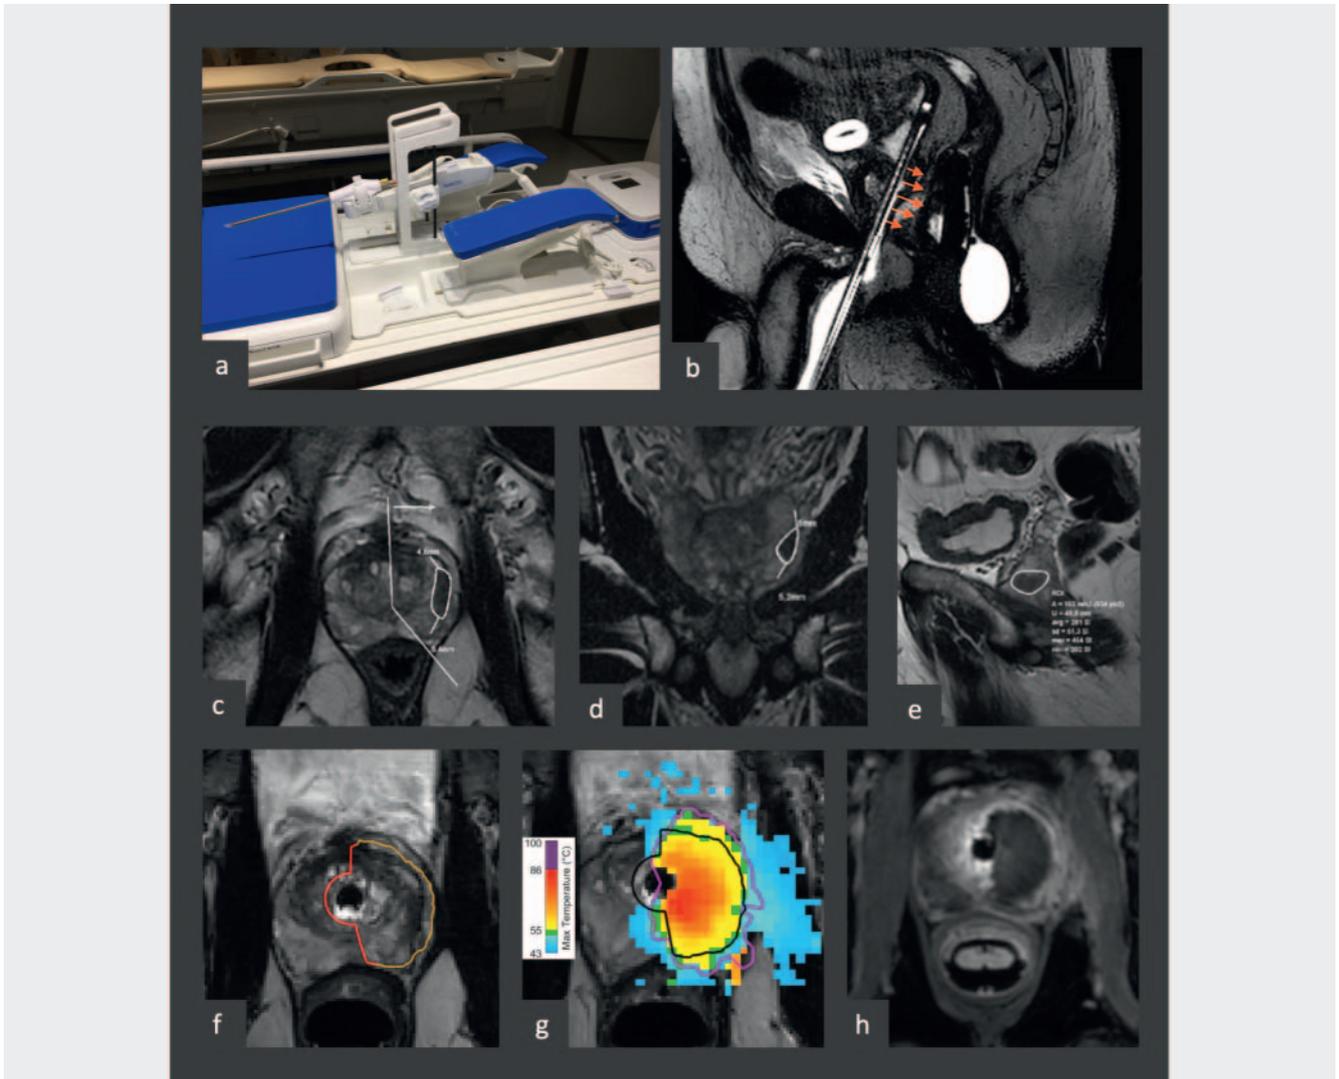

High-intensity focused ultrasound (HIFU) can be used to noninvasively ablate deep-seated tissue. The procedure is usually carried out under image guidance using either diagnostic ultrasound (US-HIFU) or magnetic resonance imaging (MR-HIFU) to provide spatial targeting and to monitor the ablation process in real time. Both US-HIFU and MR-HIFU are clinically used and approved for various applications with several emerging applications currently being evaluated in clinical trials. In the first part of this review (Magnetic Resonance-Guided High-Intensity Focused Ultrasound (MR-HIFU): Technical Background and Overview of Current Clinical Applications (Part 1)), we recently discussed the technical details of HIFU including the two image guidance approaches and subsequently reviewed the main clinical applications of MR-guided HIFU applications. In short, MR guidance provides anatomical images with high soft-tissue contrast and offers the additional advantage of near real-time temperature mapping which allows delivery of well-defined thermal doses while protecting heat-sensitive structures. In this second part, we will review several new and emerging applications, however again limited to MR-HIFU. Since important US-guided HIFU studies exist for some applications, we will refer interested readers to relevant reviews.

Prostate

In the last decades, prostate-specific antigen (PSA) screening has improved the detection of prostate cancer, particularly of localized low- and intermediate-risk prostate cancer (PCa) [1]. Beside the increased incidence of PCa, the precise mortality benefit of early detection is still unclear and controversially discussed. This observation could be partly explained by the detection of primarily low- and intermediate-risk prostate carcinomas and the low disease-specific ten-year mortality or elderly men with a life expectancy of less than ten years [2, 3]. The Prostate Cancer Intervention Versus Observation Trial (PIVOT) found that prostatectomy for PSA-diagnosed low-risk PCa might provide only limited benefit [4], and the Scandinavian Prostate Cancer Group Study Number Four (SPCG-4) found that prostatectomy is only beneficial for patients under 65 years of age with clinically diagnosed PCa [5]. Thus, in addition to radical prostatectomy and external-beam radiation therapy (EBRT), conservative strategies, such as active surveillance and watchful waiting, are gaining increasing importance for personalized clinical management for low- and

intermediate-risk cancer patients. Even if conservative management is indicated, some patients (up to 5–10%) still prefer a more radical approach [6], such as a radical prostatectomy, despite its associated complication rates with remaining incontinence in up to 31% [7] and erectile dysfunction in up to 50% [8]. Hence, less invasive interventional therapies, such as HIFU, are gaining importance for whole-gland or focal treatment of prostate cancer. For example, the 2016 EAU-ESTRO-SIOG guidelines state that even though focal therapy for localized PCa remains experimental due to the lack of convincing long-term results, salvage HIFU is a recommended thermal ablation option for radiation-recurrent PCa [9]. In addition, despite multifocal occurrence of PCa [10], up to one third of patients with localized prostate cancer have unilateral disease that may be suitable for focal treatment, e. g. targeted ablation, hemiablation or zonal ablation. Recently, the French Urological Association evaluated US-HIFU hemiablation for the primary treatment of low- and intermediate-risk PCa in the prospective multi-institutional IDEAL study [11]. The results revealed a 95% absence of clinically significant cancer associated with a low morbidity after 1 year, and a radical treatment-free survival rate of 89% after 2 years. After 1 year, continence and erectile functions were preserved in 97% and 78%, respectively, and severe adverse events (grade ≥ 3) were reported in only 13%.

So far, the most common HIFU approaches in prostate cancer treatment employ transrectal ultrasound-guided (US-) HIFU transducers (Ablatherm[®], Sonablate[®], FocalOne[®]), with their efficacy being well reviewed by Chaussy CG and Thüroff S [12]. The main drawback of these US-HIFU systems is the missing visualization of the target lesion and the missing real-time temperature control during ablation. In contrast, MRI allows visualization of the target lesion and provides real-time temperature mapping to deliver well-defined and well-controlled thermal doses during HIFU therapy. Thus, MR-HIFU seems to be the preferred imaging modality for guiding HIFU intervention compared to US-HIFU [13–15]. The current clinically available MR-HIFU transducers are the ExAblate[®] system (Insightec, Haifa, Israel) with a transrectal probe and the TULSA-PRO[®] (Profound Medical, Mississauga, Canada) with a transurethral probe. Both systems received CE label and are currently under clinical evaluation or collecting post-treatment data in multi-national clinical trials for localized (up to 50% of prostate volume) ablation (ExAblate[®]) and whole-gland ablation (TULSA-PRO[®]) in patients with localized, organ-confined prostate cancer (TACT trial inclusion closed).

In a prospective single-center phase I clinical trial using the MRI-guided ExAblate® transrectal HIFU probe, 8 men with 10 lesions with low- and intermediate-risk prostate cancer (Gleason 6–7) were treated and followed for 6 months [16]. All patients were discharged within 4 hours after treatment. Only one patient developed a urinary tract infection and prostatitis, the other patients did not show any complications in the follow-up

examinations. In one patient, treatment failed with significant residual disease and the need for prostatectomy and 4 out of 10 lesions revealed residual malignant tissue in the biopsy 6 months after treatment that could not be recognized on MRI. Although this study was limited by a small sample size and short follow-up, it still showed the transrectal MR-HIFU approach to be safe with low complication rates and an acceptable oncologic

outcome. In a further prospective phase I clinical trial using the MRI-guided ExAblate® transrectal HIFU probe, 14 men with low-volume low-grade prostate cancer (Gleason 6) underwent treatment with 12 men completing a 2-year follow-up [17]. The mean sonication time was 117 min with all patients tolerating the procedure well. One patient developed acute urinary retention after treatment, probably due to a urinary tract infection and another patient developed epididymo-orchitis, both complications resolved quickly under treatment with antibiotics. The median overall satisfaction at 6 months was high. At 24 months, sexual function was the only parameter to show a trend toward decline from baseline, however, not significantly. The median PSA decreased by 38.8% and remained low except in one patient who eventually underwent radiation therapy. After 6 and 24 months, none of the patients had positive multiparametric MR imaging findings. However, template biopsy at 24 months revealed 2 patients with residual tumor in the treated prostate tissue. Nevertheless, this study also demonstrated transrectal HIFU to be feasible with a favorable safety and functional profile, even though the sample size was small.

For the transurethral TULSA-PRO® system, an initial treat and resect study showed good agreement between the delineated tissue in the temperature maps acquired during treatment studies and the extent of necrotic tissue as found in histology. In this pilot study, five men with localized prostate cancer on multiparametric MRI were treated by focal MR-HIFU prior to radical prostatectomy [18]. After prostatectomy, whole mount histological sections demonstrated successful focal MR-HIFU treatment with target volumes of 4–20 ml within radii of up to 35 mm from the urethra with a mean spatial targeting accuracy of 1.5 ± 2.8 mm. The mean treatment accuracy with respect to histology was 0.4 ± 1.7 mm with all index tumors being inside the histological outer limit of thermal injury and completely covered by the targeted focal HIFU ablation. In a subsequent prospective multinational phase I clinical trial, 30 men with low- and intermediate-risk prostate cancer (Gleason 6 or 7a) were treated using the MRI-guided TULSA-PRO® transurethral HIFU transducer and followed over one year [19]. The median treatment time was 36 min and 29 participants were successfully discharged already after 24 hours. Treatment-related adverse events included

urinary tract infections (33%), acute urinary retention (27%), and epididymitis (3%). No intraoperative complications, rectal injuries, fistulas or severe post-therapeutic urinary incontinence was observed. After 1 year only one patient had low-grade urinary incontinence. The median pretreatment erectile function remained widely stable with 13 before treatment (IQR: 6 – 28) compared to 13 (IQR: 5 – 25) at the 12-month follow-up. The median PSA decreased by 87% at the 1-month control and was stable at 0.8 ng/ml (IQR: 0.6 – 1.1) to 12 months. However, in this clinical safety and feasibility study with the therapeutic intent of conservative whole-gland ablation including a 3 mm safety margin towards the capsule, residual viable tumor was found in 55% of the patients at the 1-year control.

Anyway, the available data for MR-guided HIFU are still very limited and have not yet been fully analyzed. In general, the majority of prostate cancers are situated in the posterior aspect of the peripheral zone near by the rectal wall and neurovascular bundle and some other less frequent tumors are located at the anterior fibromuscular stroma. In the comparison of both techniques, the theoretical advantage of the transurethral TULSA-PRO® approach is related to the fact that these lesions might be better ablated up to the prostate capsule with a lower risk of harming the rectum wall and neurovascular bundle in the far field and to be closer to the anterior stroma with fewer side effects in the near field [20]. Moreover, the transurethral approach allows for simultaneous placement of a rectal cooling device even further lowering the risk of rectal injuries and fistula. A disadvantage of the

transurethral approach is the risk for urethral injuries during insertion of the catheter or during sonication, which, however, has been shown to be a rare complication. On the other hand, the transrectal ExAblate® system seems to be easier to place within the rectum and allows overtreatment outside the prostate capsule, e. g. in the case of extraprostatic infiltration. However, the safety margin towards the rectal wall in the direct near field of the transducer implicates the higher risk of residual tumor tissue at the most common PCa location at the posterior peripheral zone adjacent to the prostate capsule.

An exemplary workflow for prostate ablation using the TULSA-PRO® is shown in ► Fig. 1a – h.

Altogether, MR-HIFU seems to be a promising treatment option for clinically low- to intermediate-risk prostate cancer detected on MRI and for salvage ablation of radiation-recurrent PCa. Nevertheless, further studies are needed to compare the efficacy, local recurrence and risk of complications of both currently available MR-HIFU procedures for prostate cancer treatment.

It should be noted that the clinical use of MR-HIFU is accepted in the current S3-guideline for prostate cancer when performed under study conditions with the patient still needing active surveillance after treatment.

Breast

Early stage, localized breast cancer presents a potential application for minimally invasive and local ablative techniques such as radiofrequency, microwave, laser, cryo and HIFU techniques. The current clinical standard for low-stage invasive breast carcinomas is local resection in a breast-conserving manner with high cure rates and long-term survival of more than 90% [21]. Comparable to local resection, ablative techniques seem feasible as long as a safety margin of at least 10 mm is observed and other relevant criteria such as histology, hormone receptor status, assessment of sentinel lymph node and post-interventional therapy standards are met [22]. A challenge for all ablative techniques is to achieve total tumor ablation including a safety margin, while no post-interventional histological assessment of the tumor rim is available for confirmation. Clinical outcomes comparing the above-mentioned ablative techniques for the treatment of breast cancer were recently summarized and analyzed by Peek et al. [23]. Overall, few studies have been performed with low patient numbers, which makes a systematic comparison of all techniques with respect to outcome and side effects difficult. From the total 1627 patients included in the analysis, 227 patients were treated with MR-HIFU.

MR-HIFU treatment of breast fibroadenomas was first reported by Hynynen et al. [24], demonstrating 8 complete or partial ablations of a total of 11 treated lesions. Patients were placed on the HIFU system and sonicated from anterior, while a water bag provided acoustic coupling. Most clinical MR-HIFU studies to date have been performed with anterior sonication using the commercial MR-HIFU ExAblate® system (InSightec, Haifa, Israel) [25, 26]. In the case of anterior sonication, attention has to be paid to prevent structures in the far field from heating, such as the pectoral muscle, ribs, or lung tissue (tissue/air interface), all limiting possi-

ble target locations, while near field heating led to skin burns in some cases. Clinical data showed that several tumors could not be entirely ablated, possibly due to the fact that not enough acoustic energy could be deposited due to the above-mentioned limitations or due to misplacement of the HIFU focus point [24]. Nevertheless, the outcome achieved with MR-HIFU was comparable to other ablation techniques, while the side effects were lower. A different approach is based on the lateral sonication of the tumor using dedicated large aperture breast HIFU transducers that have been developed with a different geometry (► Fig. 2a – d) [27 – 29]. Merckel et al. demonstrated partial ablation of breast cancer lesions in a treat and resect study with such a dedicated breast HIFU system (prototype, Profound Medical, Mississauga, Canada) [30]. Partial ablation was intended in order to compare treatment planning to temperature maps obtained during ablation and to ablated margins in overlay with histology sections. Results showed that lesion size correlated with applied overall acoustic energy although the achieved absolute temperatures differed per patients. Temperature feedback during ablation and calculation of thermal dose was complicated by poor temperature maps obtained by proton-resonance frequency shift (PRFS) thermometry for reasons such as breathing-induced motion and the presence of mostly fatty tissue (► Fig. 3a – h). Overall, MR-HIFU for the treatment of breast cancer can be considered a technically safe and patient-friendly method. However, before MR-HIFU could be considered as a treatment option for early stage and localized tumors, the technology needs to be further developed to guarantee complete tumor ablation including the necessary safety margin by improving image guidance and temperature mapping [31].

Abdominal Applications

US-HIFU has been used in several studies for the ablation of benign and malignant tumors in abdominal organs with good success rates, thus establishing an alternative to other minimally invasive thermal ablation methods for a selected group of patients. In general, treatments reveal partial or complete tumor ablation and are associated with comparably low side effects and complications [32 – 34]. However, especially for liver tumors, HIFU ablation has yet to be benchmarked against other minimally invasive procedures such as radiofrequency and microwave ablation, or transarterial chemoembolization in a multi-arm study which is currently not available.

For MR-HIFU, only a few case studies have been reported so far for the ablation of liver or pancreatic tumors [35]. MR-HIFU treatment of malignancies in abdominal organs, such as the liver, pancreas or kidney, is complicated by motion and often the acoustic beam path is obstructed by the thoracic cage or air-filled cavities in the bowel system. Respiratory motion, organ motion and bowel motion exacerbate focusing of the target tissue and the reliability of MR thermometry [36]. However, with new experimental approaches, respiratory excursion can be controlled by high-frequency jet ventilation [37] or apnea breaks for gated sonication [38]. Image guidance and navigator techniques allow tracking of organ movement to apply HIFU when the target is in a defined position or also to follow the movement

of the target with the focus point [39–41]. Another technique currently under development is “beam-shaping” which excludes the ribs from the beam path thus protecting the patient from uncontrolled heating of the chest wall [42]. For the ablation of lesions in the liver dome, an iatrogenic intrapleural fluid infusion resulting in a pleural effusion could provide the necessary acoustic window [43]. While several studies using ultrasound-guided HIFU for the ablation of liver malignancies exist [44], only few case studies using MR-guided HIFU and demonstrating the feasibility of this approach have been published (► Fig. 4a–e).

Ductal pancreatic cancer still has a particularly bad prognosis with a 2-year survival rate of less than 10%. When diagnosed, 40% of these tumors have already metastasized, and in 60% of patients the tumor is locally inoperable due to infiltration of the portal vein, celiac trunk or superior mesenteric artery. In addition to radio-chemotherapy and a palliative operation, ablative procedures can help to control local tumor growth and reduce pain thereby improving the quality of life. So far, more than 1200 pancreatic cancer patients have been treated with US-HIFU, showing that this ablation method is safe with very few adverse events, provides pain palliation, and possibly extends life expectancy [33, 45–47]. A HIFU therapy of the pancreas is challenging because of air-filled bowel loops being present in the acoustic path. Thus, preparatory measures such as fasting, clyster or a nasogastric tube are important. Contact of the tumor with the duodenum or the bile duct can be a further contraindication for HIFU. While ultrasound guidance has the advantage that the acoustic beam path and possible obstructions by air pockets in the stomach or bowel can be directly probed, targeting of the pancreatic lesion is complicated due to the low intrinsic tissue contrast. Furthermore, heating to an ablative temperature is difficult to monitor as thermometry methods are lacking. Few case reports using MR-HIFU showed the feasibility of performing similar treatments under MR guidance [48]. For MR-HIFU therapy, patients are typically placed in a prone position on the system using, if necessary, an acoustically transparent dome-shaped gel pad or water-filled device to displace stomach and bowel that may potentially block the beam path. An example for MR-HIFU ablation of a pancreatic tumor is shown in ► Fig. 5a–e [48].

Similarly, ablation of renal cancer using US-HIFU has been sporadically performed indicating that ablation is possible in principle [49, 50].

Conclusion

Currently, the clinical use of MR-HIFU is restricted to thermal ablation of tissues and is clinically established for the treatment of uterine fibroids, pain alleviation of bone metastases and treatment of central tremor. Other promising applications in oncology either with curative intent or in a palliative setting are currently the subject of preclinical and clinical studies. One prominent and promising example is the treatment of prostate cancer using either a transrectal or transurethral probe, both of which recently received CE approval. As a noninvasive method, MR-HIFU treatments are patient-friendly with low complication rates and minor side effects

and can be repeated if needed. Integration with MRI provides real-time spatial guidance, which further improves safety and therapeutic outcome. MRI-based temperature mapping offers the option for closed-loop temperature feedback for the delivery of well-defined thermal doses which allows protection of crucial structures from overheating while delivering a lethal thermal dose to the target tissue. While clinical pilot studies do exist for several new applications, prospective multi-arm clinical trials are urgently needed to demonstrate improved outcome compared to standard treatments.

Conflict of Interest

The authors declare that they have no conflict of interest.
