## Abstract

Emicizumab, a bispecific monoclonal antibody, bridges activated factor IX (FIXa) and FX, replacing the function of missing FVIIIa to restore effective hemostasis in persons with hemophilia A (PwHA). Here we assess pharmacokinetic (PK) and pharmacodynamic (PD) biomarkers in PwHA with FVIII inhibitors in the Phase III HAVEN 1 study (NCT02622321). Blood samples from 112 PwHA receiving 1.5 mg/kg once-weekly subcutaneous emicizumab were analyzed at central laboratories. Emicizumab concentrations for PK analysis were measured via validated immunoassay. PD effects were assessed using FVIII chromogenic activity assay containing human factors (Hyphen Biophen FVIII:C), and by FXIa-triggered thrombin generation (TG). Activated partial thromboplastin time (aPTT), prothrombin time (PT), antigen levels of FIX and FX, fibrinogen, D-dimer, and prothrombin fragment 1.2 (PF1.2) levels were determined. Emicizumab trough concentrations  $\geq 50$   $\mu\text{g/mL}$  were maintained throughout the study. FVIII-like activity and TG (peak height) correlated with emicizumab concentrations and remained above 20 U/dL and 100 nM, respectively, with a weekly maintenance dose, theoretically converting persons with severe hemophilia A to a mild disease phenotype. aPTT was normalized at subtherapeutic concentrations of

emicizumab. Plasma concentrations of target antigens FIX and FX were not significantly affected by emicizumab treatment; nor were fibrinogen, PT (international normalized ratio), D-dimer, or PF1.2. The PK profile of once-weekly emicizumab in HAVEN 1 provides sustained therapeutic plasma levels, consistent with population PK models. Both the PK profile and the PD and safety biomarkers are consistent with the established efficacy of emicizumab prophylaxis in PwHA with FVIII inhibitors.

## Introduction

Hemophilia A results from congenital deficiency of coagulation factor (F) VIII.<sup>1</sup> Persons with hemophilia A (PwHA) can experience frequent clinical bleeding-related symptoms including easy bruising, prolonged bleeding after trauma or surgery, and spontaneous bleeding into joints, muscles, or soft tissues.

The current standard of care for PwHA with a frequent bleeding phenotype (mostly severe hemophilia) is regular prophylactic intravenous infusions of FVIII,<sup>1,2</sup> the goal being to maintain target trough FVIII activity levels of  $\geq 1$  U/dL to prevent bleeds and mitigate long-term secondary complications. Approximately 30% of PwHA develop neutralizing alloantibodies (FVIII inhibitors), which render FVIII replacement therapy ineffective.<sup>1</sup> Prior to the availability of emicizumab, hemostatic treatments for PwHA with FVIII inhibitors were prothrombotic coagulation factors that bypass FVIII. However, bypassing agents (BPAs) such as activated prothrombin complex concentrate (aPCC) and recombinant-activated human FVII (rFVIIa) have suboptimal hemostatic effects and a high treatment burden associated with significant limitations (short half-life, slow intravenous infusion rate).<sup>3,4</sup>

Emicizumab (HEMLIBRA<sup>®</sup>; F. Hoffmann-La Roche Ltd, Basel, Switzerland) is a bispecific, humanized, monoclonal antibody that bridges activated FIX (FIXa) and FX, mimicking the cofactor function of missing activated FVIII (FVIIIa), to restore effective hemostasis in PwHA.<sup>5,6</sup> It has no sequence homology with FVIII, and is therefore unlikely to induce FVIII inhibitors and is unaffected by their presence.<sup>5,7</sup> Emicizumab has high subcutaneous bioavailability<sup>8</sup> and a half-life of approximately 30 days,<sup>9</sup> enabling treatment with once weekly,<sup>10</sup> every 2 week,<sup>11</sup> or every 4 week<sup>12</sup> subcutaneous dosing regimens, thus avoiding the need for frequent intravenous administration.

Following the results of HAVEN 1<sup>10</sup> and HAVEN 2,<sup>13,14</sup> 1.5 mg/kg subcutaneous once-weekly emicizumab was approved as a prophylactic treatment for PwHA with FVIII inhibitors of all age groups in several countries (including European Union member states). The original indication and dosing of emicizumab has now been expanded in many countries based on the results of HAVEN 3<sup>11</sup> and HAVEN 4<sup>12</sup> to include 1.5 mg/kg once weekly, 3.0 mg/kg every 2 week, or 6.0 mg/kg every 4 week prophylaxis for PwHA regardless of their inhibitor status. The European Medicines Agency has approved emicizumab for use in patients without FVIII inhibitors only for those with severe ( $< 1$  U/dL FVIII activity) hemophilia A.<sup>15,16</sup>

HAVEN 1<sup>10</sup> was a pivotal Phase III study designed to evaluate the efficacy, safety, and pharmacokinetics (PK) of subcutaneous once-weekly emicizumab prophylaxis versus no prophylaxis in

adult and adolescent (aged  $\geq 12$  years) PwHA with FVIII inhibitors. Emicizumab was well tolerated and demonstrated an 87% reduction in treated bleed annualized bleeding rate (ABR) versus no prophylaxis (ABR [95% confidence interval [CI]] 2.9 [1.69–5.02] vs. 23.3 [12.33–43.89]). Of those treated with emicizumab, 62.9% experienced zero treated bleeds. Emicizumab improves upon current treatment options and fulfills a previously unmet medical need.<sup>11,12,17,18</sup>

While emicizumab mimics FVIII cofactor activity, it has fundamental differences from FVIII in terms of PK and biochemical and pharmacological properties.<sup>19</sup> This article presents the secondary objectives assessing PK, pharmacodynamic (PD), and safety biomarkers from HAVEN 1.

## Methods

### Study Design and Patients

#### Patients

Adult and adolescent ( $\geq 12$  years old) PwHA with FVIII inhibitors previously treated with BPAs with suboptimal success were enrolled based on a comprehensive list of inclusion and exclusion criteria.<sup>10</sup>

Participants ( $n = 113$ ) were enrolled between November 18, 2015 and September 28, 2016; the clinical cut-off date for this analysis was September 8, 2017. All participants provided written informed consent prior to study entry. The study protocol was approved by the relevant independent ethics committee/institutional review board at each participating institution and was conducted in accordance with the principles of the Declaration of Helsinki and Good Clinical Practice.

#### Study Design

HAVEN 1, a Phase III, open-label, multicenter, randomized study in PwHA with FVIII inhibitors, took place at 43 centers across 14 countries. Full methods of the HAVEN 1 study have been published previously.<sup>10</sup> Briefly, participants receiving episodic BPA treatment before study entry were randomized 2:1 to receive either emicizumab prophylaxis (arm A) or no prophylaxis (arm B). Participants previously treated with prophylactic BPAs were assigned to arm C to receive emicizumab prophylaxis. Participants from a noninterventional study (NCT02476942)<sup>20</sup> who were unable to enroll in arms A, B, or C before enrollment was closed were eligible for arm D.

PwHA in arms A, C, and D were given a loading dose of subcutaneous emicizumab 3 mg/kg once weekly for 4 weeks, followed by 1.5 mg/kg subcutaneous once weekly maintenance thereafter; PwHA in arm B received no prophylaxis. After completing  $\geq 24$  weeks in the study, arm B participants

could receive emicizumab prophylaxis as described (i.e., 3 mg/kg once weekly for 4 weeks, 1.5 mg/kg once weekly thereafter). All participants could receive episodic BPAs for the treatment of breakthrough bleeding, as needed. In case of suboptimal efficacy after  $\geq 6$  months of emicizumab prophylaxis, uptitration to 3 mg/kg once weekly was permitted.<sup>10</sup> Approved subcutaneous administration sites were the abdomen, upper arm, and thigh.

### Blood Sampling and Analyses

Blood samples for PK and PD analyses were taken from all participants at the following scheduled time points: before first emicizumab dose; immediately prior to emicizumab injection (at trough) every week for the first month; every 2 weeks for the second month; every 4 weeks from the third to the sixth month; every 8 weeks from the seventh to the twelfth month; and every 12 weeks thereafter. Following thrombotic microangiopathy and thromboembolism in two participants treated with an average cumulative aPCC dose of  $\geq 100$  U/kg/24 hours while receiving emicizumab prophylaxis, the HAVEN 1 protocol was amended to recommend the optional collection of additional samples for platelet count, D-dimer, prothrombin fragment 1.2 (PF1.2), and fibrinogen analysis within 24 hours of BPA use from October 2016 onwards.

Blood samples (2 mL) for emicizumab measurement were collected using ethylenediaminetetraacetic acid-containing plastic tubes. Samples were centrifuged ( $1,500 \times g$ ,  $4^\circ\text{C}$ ) for 15 minutes to collect plasma and were stored below  $-70^\circ\text{C}$  prior to analysis.

Blood samples (5.4–18.9 mL depending on body weight) were collected in plastic tubes containing 3.2% sodium citrate for analysis of: FVIII activity, thrombin generation (TG), activated partial thromboplastin time (aPTT), prothrombin time (PT), FIX and FX antigens, D-dimer, PF1.2, fibrinogen, and von Willebrand factor antigen (VWF:Ag). Samples were centrifuged ( $3,000 \times g$ , room temperature) for 20 minutes to obtain plasma and samples were stored below  $-70^\circ\text{C}$  prior to analysis.

Emicizumab plasma concentrations were determined using a validated enzyme-linked immunosorbent assay, performed by QPS Netherlands B.V. (Groningen, The Netherlands). The lower limit of quantitation was 100 ng/mL in human plasma. Assay precision and accuracy were 9.5 to 13.3% and 97.6 to 103%, respectively.

All biomarkers (except platelet count) were analyzed at Medpace Reference Laboratories (Cincinnati, Ohio, United States). FVIII activity of emicizumab was measured using a validated chromogenic assay containing human FIXa and FX (Hyphen Biomed, Neuville-sur-Oise, France) with two different calibration curves: high, for samples with  $\geq 10$  U/dL FVIII activity; and low, for samples with  $< 10$  U/dL FVIII activity. Human-derived factors were used in the chromogenic assays as bovine-derived components are insensitive to emicizumab, and therefore cannot be used to measure emicizumab activity.<sup>21</sup> Of note, FVIII activity reported for PwHA treated with emicizumab with this assay cannot be compared with, or interpreted as equivalent to, FVIII activity reported in participants treated with FVIII; it will, therefore, be called FVIII-like activity throughout the rest

of the article. TG was measured with the Calibrated Automated Thrombogram method (Diagnostica Stago, Asnières-sur-Seine, France), which used a triggering reagent containing FXIa, as this has been shown to be more robust and sensitive than tissue factor, especially for those with low apparent FVIII activities, as would be expected in HAVEN 1 participants (0–30 U/dL FVIII).<sup>22</sup> TG (peak height) was derived from the thrombogram. Clotting times (aPTT and PT), D-dimer, PF1.2, fibrinogen, and VWF:Ag were analyzed using commercial test kits approved for in vitro diagnostic use according to the manufacturers' kit inserts (see **Supplementary Material**, available in the online version). Protein levels of both FIX and FX were measured using validated immunoassays (Assaypro, St. Charles, Missouri, United States). Platelet count was measured at the local clinical sites as part of regular safety monitoring and was recommended to be measured within 24 hours of BPA administration.

### Pharmacokinetics/Pharmacodynamics Analysis

Exploratory graphical analyses were performed to investigate the PK/PD relationship between emicizumab concentration and FVIII-like activity, TG, or aPTT. The data from all participants were pooled for analysis. With only trough samples, hysteresis could not be checked in the present study. However, as indicated in previous studies in healthy subjects<sup>23</sup> and in PwHA,<sup>6</sup> PD markers (e.g., aPTT or TG) are directly linked to emicizumab concentration without time delay (i.e., no hysteresis). Therefore, a direct relationship between PK and PD effect was considered.

The PK/PD relationships for TG and FVIII-like activity could not be appropriately described by a maximum effect ( $E_{\max}$ ) model due to the limited range of emicizumab concentrations achieved in the HAVEN 1 study. Linear regressions were, therefore, performed on the “linear” portion of the  $E_{\max}$  model (i.e., for concentrations up to 80  $\mu\text{g/mL}$ ).

For aPTT, different inhibitory  $E_{\max}$  models were tested for best fit, and an appropriate model was selected on the basis of the Akaike information criterion. Model diagnosis was also performed by visual analysis of the weighted residual plots and by observation of the relative standard error of the estimated variables. The estimates and associated relative standard error were reported. The relationships between emicizumab plasma concentration and aPTT were well described by an inhibitory  $E_{\max}$  model:

$$E = E_0 - \frac{I_{\max} \cdot C}{C + IC_{50}}$$

Here,  $E$  is the aPTT,  $E_0$  is the aPTT at baseline (seconds),  $I_{\max}$  is the maximum inhibition at infinite emicizumab concentration,  $C$  is the emicizumab plasma concentration ( $\mu\text{g/mL}$ ), and  $IC_{50}$  is the emicizumab concentration causing half of the maximum effect ( $\mu\text{g/mL}$ ) (**Supplementary Table S1**, available in the online version).

Graphical investigations of the potential effects of average FIX and FX concentrations (emicizumab target antigens) on the PK/PD relationships were also performed.

Of note, investigation of the relationship between emicizumab exposure and bleeding events is the subject of dedicated publications.<sup>9,24,25</sup>

### Statistical Analysis

The total HAVEN 1 sample size was based on clinical rather than statistical considerations, taking into account the limited number of PwHA with FVIII inhibitors available for participation, and to collect sufficient data to assess the safety and efficacy of emicizumab as previously described.<sup>10</sup>

All participants initially received the same emicizumab dosing regimen. Consequently, PK and PD data are presented as a single-dose group. Since participants in arm B switched to emicizumab prophylaxis after completing 24 weeks on study, their scheduled time relative to first emicizumab dose was used for graphical displays. PK and PD data were subject to descriptive analysis. Data from participants who uptitrated to 3 mg/kg once-weekly emicizumab were included in the descriptive statistics until uptitration, and continued to be included in the PK/PD relationship plots after uptitration. PD data in the form of aPTT and TG from participants who had their blood samples drawn via ports and for whom contamination with heparin was suspected were excluded from the summary statistics calculations.

### Data Sharing Statement

Data sharing statement: Qualified researchers may request access to individual patient-level data through the clinical study data request platform ([www.clinicalstudydatarequest.com](http://www.clinicalstudydatarequest.com)). Further details on Roche's criteria for eligible studies are available at <https://clinicalstudydatarequest.com/Study-Sponsors/Study-Sponsors-Roche.aspx>. For further details on Roche's Global Policy on the Sharing of Clinical Information and how to request access to related clinical study documents, visit [https://www.roche.com/research\\_and\\_development/who\\_we\\_are\\_how\\_we\\_work/clinical\\_trials/our\\_commitment\\_to\\_data\\_sharing.htm](https://www.roche.com/research_and_development/who_we_are_how_we_work/clinical_trials/our_commitment_to_data_sharing.htm).

## Results

### Study Population

A full description of participants enrolled in the HAVEN 1 study, together with baseline demographics and clinical characteristics of each treatment arm, has been published previously.<sup>10</sup> Briefly, 113 male participants with a median age of 29 years (range: 12–75 years) were enrolled in HAVEN 1; all participants had a historic FVIII inhibitor titer  $\geq 5$  Bethesda Units per mL (BU/mL) (range: 5–5,000 BU/mL), 106 (93.8%) had a diagnosis of severe congenital hemophilia A, and 69.6% (78 of 112) had target joints. The median duration of exposure to emicizumab was 60.5 weeks (range: 3.3–94.2 weeks). For this analysis, since the primary analysis clinical cut-off date (October 25, 2016)<sup>10</sup> the five outstanding participants in arm B were switched to emicizumab prophylaxis and are now included in the analysis population, and four additional participants have enrolled in arm D. One participant withdrew from the study without receiving any

emicizumab treatment, and five participants were withdrawn from emicizumab treatment; three due to adverse events and two following physician or patient decision (**► Supplementary Fig. S1**, available in the online version).

### Pharmacokinetics

At clinical data cut-off, 112 PwHA who had received at least one emicizumab dose and had at least one postdose emicizumab concentration sample were included in the PK analysis. Mean emicizumab trough concentration ( $C_{\text{trough}}$ ) increased with once weekly subcutaneous doses of 3 mg/kg emicizumab (loading dose); by the end of the loading dose period (week 5), a mean  $C_{\text{trough}}$  of 54.1  $\mu\text{g/mL}$  (median [interquartile range [IQR, 25th and 75th percentiles]]: 52.7 [44.5–62.8]  $\mu\text{g/mL}$ ) was achieved (**► Fig. 1**). During the maintenance dose phase,  $C_{\text{trough}}$  was sustained slightly above 50  $\mu\text{g/mL}$  with 1.5 mg/kg once weekly subcutaneous emicizumab. The data variability was moderate, with an IQR of 41.6 to 61.6  $\mu\text{g/mL}$ .

### Pharmacodynamics

#### FVIII-Like Chromogenic Activity

As expected in participants with FVIII deficiency, there was no detectable FVIII activity in PwHA at baseline (**► Fig. 2A**), except for one participant with mild hemophilia who presented with 15 U/dL FVIII-like activity at baseline. The participant, who had a highest historical FVIII inhibitor titer of 18 BU/mL, presented with a baseline FVIII inhibitor titer of 17 BU/mL and lacked documented coagulation factor use immediately prior to sampling. This participant, who has a missense mutation of the *F8* gene (Arg2150His), may have developed alloantibodies against exogenous (wild-type) FVIII, but not against his own mutated, dysfunctional, endogenous FVIII, as previously reported with this mutation.<sup>26</sup>

As measured using a validated chromogenic assay containing human FIXa and FX, mean FVIII-like activity increased to 29.8 U/dL (95% CI, 15.2–44.3) among the study population ( $n = 112$ ) at the end of the emicizumab loading dose period, and stabilized above 20 U/dL thereafter; at week 72, mean FVIII-like activity was 20.3 U/dL (95% CI, 12.3–28.4).

#### Thrombin Generation

As expected for PwHA with high FVIII inhibitor titers, there was no detectable TG at baseline (**► Fig. 2B**), except for one participant in whom a peak height of 165 nM was reported (the same participant with a history of mild hemophilia who exhibited 15 U/dL FVIII-like activity at baseline).

Following the emicizumab loading dose phase, mean TG peak height increased on average among the study population to 108.8 nM (95% CI, 29.7–187.9) and was sustained thereafter; at week 72, mean TG peak height was 108.7 nM (95% CI, 46.3–171.1).

Of note, six participants had no detectable TG at some or all time points despite treatment with emicizumab. In these participants, blood samples were drawn via a port, and contamination with heparin was later confirmed. These blood samples did exhibit chromogenic FVIII-like activity

**Fig. 1** Trough plasma concentration of emicizumab (mean  $\pm$  standard deviation) after 4 loading doses of 3 mg/kg once-weekly (QW) subcutaneous (SC) for 4 weeks, followed by maintenance dosing of 1.5 mg/kg QW SC. Means were derived from the values of participants of all emicizumab-treated arms ( $n = 112$ ). For patients in arm B ( $n = 18$ ) who switched to emicizumab prophylaxis after 24 weeks, scheduled time relative to first emicizumab dose was used for graphical displays.

consistent with the patients' emicizumab concentration and the overall population PD data.

#### Activated Partial Thromboplastin Time

aPTT was prolonged in all participants at baseline, but was normalized below 30 seconds after the first dose of emicizumab and remained largely within normal limits (laboratory-determined reference range, 23.9–40 seconds) for the entire duration of treatment (**Fig. 2C**); at week 72, mean (standard deviation) aPTT was 23.6 seconds (2.0). A few participants consistently had values just under the lower limit of the normal range. Six participants presented with some prolonged aPTT values despite treatment with emicizumab. These participants (who also had undetectable TG) had their blood samples drawn via a port, and contamination with heparin was suspected.

#### Prothrombin Time

Overall, treatment with emicizumab had no effect on PT (international normalized ratio [INR]); the majority of participants had PT between 13 and 14 seconds at baseline (corresponding to INR of 0.9–1.1) and at all subsequent visits while receiving emicizumab once weekly subcutaneously (**Fig. 2D**). A minor increase of 0.6 seconds, however, could be seen after the first dose of emicizumab.

#### Exploratory Safety Biomarkers

Treatment with emicizumab had no clinically significant effects on plasma concentrations of the target antigens of emicizumab, FIX (**Fig. 3A**) and FX (**Fig. 3B**). A few elevated values of both FIX and FX plasma concentrations were observed at baseline; these were mainly observed in participants in arm C, who had used prophylactic aPCC before entering the study. Likewise, emicizumab treatment had no clinically significant effects on D-dimer (**Fig. 3C**) or PF1.2 (**Fig. 3D**). Highly elevated D-dimer concentrations were observed on single visits in two participants who had used aPCC for the treatment of breakthrough bleeding in the 24 to 48 hours before sample collection. Isolated instances of elevated PF1.2 concentrations were also noted in a few participants, most of whom had used aPCC for treating breakthrough bleeds in the days before sample collection.

Other safety markers that were measured included platelet count (**Supplementary Fig. S2A**, available in the online version), fibrinogen (**Supplementary Fig. S2B**, available in the online version), and VWF:Ag (**Supplementary Fig. S2C**, available in the online version), all of which remained constant within expected limits from screening through to the clinical cut-off. Further safety results have been reported previously.<sup>10</sup>

**Fig. 2** Pharmacodynamic markers following once-weekly dosing with emicizumab. Chromogenic FVIII-like activity (A), peak height of thrombin generation (TG) (B), activated partial thromboplastin time (aPTT) (C), and prothrombin time (PT) (D). Dashed lines: individual profiles; red line: mean profile. ( $n = 112$  for FVIII-like activity and PT;  $n = 102$  for TG and aPTT).

### Pharmacokinetic/Pharmacodynamic Relationships

Chromogenic FVIII-like activity (measured using a FVIII chromogenic assay with human FIXa and FX) was well correlated with emicizumab plasma concentration (**Fig. 4A**). It increased linearly up to approximately 80 to 100  $\mu\text{g/mL}$  and seemed to flatten thereafter, although the scarcity of data values above 100  $\mu\text{g/mL}$  emicizumab prevented complete characterization in this range. Similar to FVIII-like activity, TG (peak height) also correlated well with emicizumab concentrations in an apparently linear fashion up to emicizumab concentrations of approximately 80 to 100  $\mu\text{g/mL}$  (**Fig. 4B**). Of note, the concentration of FIX or FX did not appear to impact the PK/PD relationships of either FVIII-like activity or TG (**Supplementary Figs. S3 and S4**, available in the online version). A concentration-dependent normalization of aPTT ( $< 40$  seconds) was observed starting at plasma emicizumab concentrations of  $\geq 5$   $\mu\text{g/mL}$ , with a maximal effect achieved at concentrations  $\geq 30$   $\mu\text{g/mL}$  (**Fig. 4C**).

### Discussion

Emicizumab is a novel and recently approved therapy for PwHA. Its biochemical and pharmacological properties enable it to address challenges faced by PwHA. Emicizumab allows for subcutaneous rather than intravenous dosing, a more convenient once weekly, every 2 week, or every 4 week administration schedule, functionality as a FVIIIa-mimicking cofactor without being affected by the presence of FVIII inhibitors

(providing effective bleed control in PwHA both with/without FVIII inhibitors), and lack of induction of FVIII inhibitors.<sup>11,23</sup>

The HAVEN 1 dosing regimen of 3 mg/kg once weekly emicizumab for 4 weeks followed by 1.5 mg/kg once weekly emicizumab thereafter was selected by population PK/efficacy modeling<sup>9</sup> to rapidly achieve and to maintain thereafter therapeutic emicizumab  $C_{\text{trough}}$ . At the end of the loading dose period, mean  $C_{\text{trough}}$  levels slightly above 50  $\mu\text{g/mL}$  were achieved on average among the study population, and were maintained thereafter with 1.5 mg/kg once weekly dosing for the entire study duration ( $> 16$  months). Owing to its long elimination half-life of approximately 1 month,<sup>23</sup> minimal peak-trough fluctuation is expected with emicizumab.<sup>9</sup> This provided sustained therapeutic exposure to emicizumab for the majority of participants. Based on an estimated potential conversion factor of 0.3 U/dL of FVIII activity per  $\mu\text{g/mL}$  of emicizumab,<sup>6</sup> a mean steady-state  $C_{\text{trough}}$  of  $\geq 50$   $\mu\text{g/mL}$  is expected to continuously provide an equivalent FVIII activity of  $\geq 15$  U/dL. This sustained level of protection, which is considered sufficient to reduce the risk of joint bleeding,<sup>27</sup> was confirmed by the substantial reduction in individual ABRs for most participants in HAVEN 1.<sup>10</sup>

Activation of FX by emicizumab/FIXa and the subsequent downstream effects on the coagulation cascade were monitored in HAVEN 1 via various PD markers. Unlike FVIII, emicizumab does not require a rate-limiting activation step but instead directly mimics the cofactor activity of FVIIIa.<sup>5</sup> Therefore, the

**Fig. 3** Safety biomarkers during once-weekly dosing with emicizumab ( $n = 112$ ). FIX antigen (A), FX antigen (B), D-dimer (C), prothrombin fragment 1 and 2 (PF1.2) (D). Dashed lines: individual profiles; red line: mean profile for FIX and FX antigen; median and interquartile range for D-dimer and prothrombin fragment 1 and 2. Upper limit of normal values: D-dimer (0.5  $\mu\text{g/mL}$ ); PF1.2 (1.2 nmol/L).

shortening effect of emicizumab on aPTT is considerably greater than that of FVIII. Consequently, conventional aPTT-based assays (1-stage) that measure FVIII activity are significantly affected by emicizumab and report artificially elevated FVIII activity.<sup>28</sup> In the present study, the FVIII-like activity of emicizumab was monitored with a chromogenic FVIII activity assay using human FIXa and FX. FVIII-like activity increased with emicizumab loading doses, achieving activity levels of approximately 30 U/dL at the end of the loading dose period (week 5). With the administration of maintenance emicizumab doses, FVIII-like activity stabilized at approximately 20 U/dL on average among the study population, corresponding to approximately 20% of the FVIII-like activity seen in healthy subjects.<sup>29</sup> The slight apparent decline in FVIII-like activity over time is thought to be the result of a signal drift in the assay (i.e., a change in signal level [FVIII activity] at a given emicizumab concentration with time), likely due to a change in the manufacture of multiple assay kits. This explanation for the artifact in the chromogenic FVIII activity assay was further supported by the absence of a similar decline or difference between groups in either emicizumab plasma concentration or TG.

Chromogenic FVIII-like activity and emicizumab concentration levels were well correlated, with a linear increase in FVIII-like activity with emicizumab plasma concentration up to 80  $\mu\text{g/mL}$  (**Supplementary Fig. S5**, available in the online version). Of note, reported FVIII-like activity for PwHA treated with emicizumab should not be interpreted as equivalent to FVIII activity reported in participants treated with FVIII. Due to the

different enzymatic cofactor properties of the two molecules, FVIII-like activity can only be used as an approximation of hemostatic emicizumab activity *in vivo*.<sup>5,19</sup> Nevertheless, the increase and steady maintenance of FVIII-like activity provides a relative indication of the procoagulant activity of emicizumab.

Similarly, TG (peak height) increased following the initiation of treatment with emicizumab. By the end of the loading dose period, TG peak height of approximately 110 nM, equivalent to 20 to 30% of that in healthy people (316–488 nM),<sup>23</sup> was observed and sustained thereafter with emicizumab 1.5 mg/kg once weekly maintenance doses. TG was well correlated with emicizumab plasma concentration (**Supplementary Fig. S6**, available in the online version). This was, however, associated with relatively large variability, possibly due in part to the concomitant use of BPAs for the treatment of breakthrough bleeding; such variability also aligns with data reported for TG values in both PwHA and healthy people.<sup>30–32</sup> These TG peak height results confirmed the procoagulant effect of emicizumab and demonstrated the ability of TG assays to provide an indication of emicizumab procoagulant activity. Although availability of TG assays is limited to specialized laboratories, this usage was evidenced by a recently published case in which TG was used to guide the management of breakthrough bleeds with BPAs in a participant receiving emicizumab.<sup>33</sup>

Comparison of the measured values of FVIII-like activity and TG peak height in this study with available reference data suggests that the procoagulant activity achieved in HAVEN 1 corresponded to approximately 15 to 30% of that

**Fig. 4** Pharmacokinetic/pharmacodynamic relationships. Correlation between emicizumab plasma concentrations and chromogenic FVIII-like activity (A), peak height of thrombin generation (B), activated partial thromboplastin time (C). (A) Gap at 10 U/dL reflects the use of two different calibration curves. (C) Line indicates model.

seen in healthy normo-coagulative people.<sup>23,29</sup> This suggests that persons with severe hemophilia A treated with emicizumab prophylaxis at a maintenance dose of 1.5 mg/kg/week could theoretically be converted to a mild hemophilia disease phenotype. Of note, similar findings have recently been obtained with human chromogenic FVIII and TG assays from direct comparisons between healthy adults, PwHA and FVIII inhibitors receiving emicizumab, and persons with mild hemophilia A without FVIII inhibitors receiving no therapy.<sup>34</sup>

FIX and FX, the target antigens of emicizumab, have the potential to impact its procoagulant activity.<sup>31</sup> However, in the range of concentrations seen in this study (FIX, 6–12 ng/mL; FX, 11–32 ng/mL), FIX and FX concentrations did not affect the PK/PD relationships between emicizumab and FVIII-like activity (► **Supplementary Fig. S3**, available in the online version) or TG (► **Supplementary Fig. S4**, available in the online version).

As reported in previous studies, emicizumab had a strong effect on aPTT.<sup>6,26</sup> aPTT was shortened to within normal limits after the first dose of emicizumab and remained largely within these limits thereafter. The normalization of aPTT at low emicizumab concentrations ( $\geq 5$  µg/mL), with an estimated  $IC_{50}$  of 1.1 µg/mL, is thought to be a direct consequence of the mechanism of action of emicizumab (as discussed above) and its resulting interference with clotting time-based assay methods.<sup>6</sup> Normalization of aPTT occurs at subtherapeutic emicizumab concentrations.<sup>9,35,36</sup> Consequently, aPTT is not an

accurate marker of hemostasis in the presence of emicizumab and should not be used to monitor emicizumab efficacy. However, in the presence of unanticipated bleeding event together with low values of FVIII-like activity, marked increase of aPTT could be an indicator of the presence of anti-emicizumab antibody or noncompliance.

Emicizumab is not expected to affect the extrinsic pathway of the coagulation cascade. However, emicizumab has potential for a modest interference effect on the activation of FX by the FVIIa-TF complex due to the binding of emicizumab to FX and subsequent steric hindrance.<sup>37</sup> De facto, a tiny increase of PT was noticed after the first dose of emicizumab. This corresponded to approximately 0.05 INR units and was not considered clinically relevant. PT remained stable thereafter throughout the duration of the study.

Owing to its low target-antigen affinity, emicizumab had no effect on FIX or FX concentrations, confirming previous findings.<sup>6</sup> Slightly elevated FIX and FX concentrations were observed, mainly at baseline (i.e., in the absence of emicizumab); these are believed to reflect previous use of aPCC containing both FIX and FX<sup>38</sup> before study entry.

In terms of the safety markers, emicizumab had no effect on D-dimer or PF1.2 levels. Overall, this is consistent with the inability of emicizumab to activate coagulation in the absence of an initiating signal. There were isolated instances in which changes in these markers were observed; however, these appeared to be related to the use of BPAs (aPCC and rFVIIa)

either before study entry or for treatment of breakthrough bleeding (► **Supplementary Fig. S7**, available in the online version). Furthermore, emicizumab had no effect on platelet count, fibrinogen, or VWF:Ag (► **Supplementary Fig. S2**, available in the online version). The absence of PT prolongation, platelet count decrease, or fibrinogen decrease in participants treated with emicizumab confirms that emicizumab alone does not induce consumptive coagulopathy. Altogether, these results were aligned with the overall safety profile of emicizumab.<sup>10–13</sup>

In conclusion, the PK profile of 1.5 mg/kg subcutaneously once weekly emicizumab in HAVEN 1 was consistent with population PK models and provides prophylactic bleed control in a majority of PwHA with FVIII inhibitors.<sup>9</sup> With regard to PD, both chromogenic FVIII-like activity and TG correlated with emicizumab concentrations and demonstrated stable activity throughout the maintenance-dosing period. Due to the differing biochemical characteristics of FVIII and emicizumab, the chromogenic FVIII assay may only be used to approximate PD effects of emicizumab in PwHA. TG, which provides a global assessment of coagulation, may have potential to confirm the pharmacological effect of emicizumab and guide BPA use in emicizumab-treated PwHA in case of surgeries or breakthrough bleeding. In addition to standardization of the TG assay, further investigations are needed to confirm this conclusion. FIX and FX levels and a panel of coagulation assays and markers including D-dimer were unaffected by emicizumab. aPTT, which is normalized at subtherapeutic emicizumab levels, should not be used to guide clinical decisions regarding PwHA receiving emicizumab. Studies are underway to determine the effects of emicizumab on different assay classes not examined here, to inform appropriate changes in clinical laboratory practice to better accommodate emicizumab.<sup>28</sup>

### What is known about this topic?

- Emicizumab, a humanized, bispecific antibody, mimics missing activated factor VIII (FVIII) function in persons with hemophilia A (PwHA).
- In the HAVEN 1 study, emicizumab administered subcutaneously once a week resulted in a decrease in the annualized bleed rate of PwHA with FVIII inhibitors when compared with on-demand and prophylactic treatment with bypassing agents.

### What does this paper add?

- During HAVEN 1, emicizumab administration provided sustained therapeutic trough plasma concentrations.
- FVIII chromogenic activity and thrombin generation assay provided an indication of emicizumab procoagulant activity.
- Based on these biomarkers, emicizumab may theoretically convert persons with severe hemophilia A to a mild disease phenotype.

### Authors' Contributions

C.S., J.I.A., C.N., M.U.C., and G.G.L. contributed to the development of the HAVEN 1 study design. C.P. and O.C. contributed to the acquisition of data for these analyses. C.S., J.I.A., J.X., C.P., O.C., G.Y., C.N., M.U.C., and G.G.L. contributed to data analysis and interpretation. All authors critically reviewed this manuscript and approved the final version for submission.

### Funding

This study was sponsored by F. Hoffmann-La Roche Ltd.

### Conflict of Interest

C.S., J.I.A., C.P., and G.G.L. are employees of F. Hoffmann-La Roche Ltd/Genentech, Inc. and hold stocks in F. Hoffmann-La Roche Ltd. J.X. is an employee of Gilead Sciences, and previous employee of F. Hoffmann-La Roche Ltd/Genentech, Inc. with stocks in F. Hoffmann-La Roche Ltd. O.C. is an employee of F. Hoffmann-La Roche Ltd. G.Y. has received grants and personal fees from Genentech, Inc./F. Hoffmann-La Roche Ltd, Takeda, and Grifols and personal fees from Novo Nordisk, UniQure, Sanofi, Spark Therapeutics, and BioMarin. C.N. has received personal fees from Bayer, CSL Behring, Freeline, LFB, Novo Nordisk, Octapharma, Pfizer, Sanofi, Shire, and Spark Therapeutics; and personal fees and other from Sobi and F. Hoffmann-La Roche Ltd. M.U.C. has received personal fees from F. Hoffmann-La Roche Ltd, Genentech, Inc., Bayer, Shire/Takeda, Pfizer, Novo Nordisk, Bioverative/Sanofi, Global Blood Therapeutics, Spark Therapeutics, BioMarin, Kedrion, Octapharma, Grifols; and has equity in Alnylam.

### Acknowledgments

Medical writing assistance for this manuscript was provided by Sophie Nobes, BSc, of Gardiner-Caldwell Communications, and was funded by F. Hoffmann-La Roche Ltd.
