# Abstract

#### **Keywords**

- bariatric surgery
- gingival crevicular fluid
- microbiota
- saliva
- periodontal disease
- mouth

The study aims to systematically review the available literature to evaluate the changes in oral microbiota in patients after bariatric surgery (BS) and correlates these alterations in microorganisms with common oral manifestations. Relevant Electronic databases were systematically searched for indexed English literature. The Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines were followed for framework designing, application, and reporting of the current systematic review. The focused PICO question was: "Is there any change in oral microbiota (O) of patients (P) who underwent BS (I) when compared with non-BS groups (C)?' Seven articles were selected for qualitative synthesis. On application of the National Institutes of Health (NIH) quality assessment tool, six studies were found to be of fair quality and one was of good quality. All the seven included studies evaluated the effect of BS on oral microbiota in humans. The outcomes of this review suggest that considerable changes take place in oral microbiota after BS which can be correlated with common oral manifestations. These changes are mainly due to the indirect effect of BS and may vary with the individuals. Due to variations in the included studies, it is difficult to proclaim any persistent pattern of oral microbiota found after BS.

# Introduction

Obesity is defined as an abnormal or excessive fat accumulation that presents a risk to health.<sup>1</sup> As per the World Health Organization (WHO), there is an increase in obese people (body mass index [BMI]  $> 30 \text{ kg/m}^2$ ) in both developed and developing countries. When compared with the year 2000,

**article published online** September 8, 2022 DOI https://doi.org/ 10.1055/s-0042-1753471. ISSN 1305-7456. there is a 1.5 times increase in obesity among adults (18 years and older) and more than two times increase in children (5–19 years) in 2016.<sup>2</sup> Thirty-nine million children under the age of 5 years were overweight or obese in 2020.<sup>3</sup> Bariatric surgery (BS) is one of the effective treatment modalities to manage morbidly obese patients and their

Inclusion criteria	Exclusion criteria
Literature in the English language	Literature in a language other than English
Human clinical studies	Animal and cadaver studies
Studies only comparing changes in oral microbiota before and after BS, irrespective of sex and age	Letter to the editor, opinion based commentaries, dissertations, review papers, abstract presentations, and incomplete trials
Studies comparing oral microbiota of patients who underwent BS with non BS group, irrespective of sex and age	Studies reporting oral microbiota post BS, without comparing it with oral microbiota before BS or in non BS groups
	Studies only comparing changes in salivary flow, chemical composition of saliva and oral health after BS
	Studies reporting changes in GI microbiota only

#### Table 1 Inclusion and exclusion criteria

Abbreviations: BS, bariatric surgery; GI, gastrointestinal.

related comorbidities in the long term.<sup>4</sup> Different types of weight reduction surgeries are documented, but the most commonly performed surgeries are Roux-en-Ygastric bypass (RYGB) and sleeve gastrectomy (SG).<sup>5</sup> Rapid loss of excessive weight due to BS improves the quality of life and decreases the mortality rate in these morbidly obese patients by reducing the related comorbidities like type-2 diabetes mellitus (DM), diabetes complications, hyperlipidemia, steatohepatitis, hypertension, cardiovascular disorders, respiratory disorders, varicose veins, and others.<sup>6,7</sup>

Various systemic manifestations associated with post-BS procedures include gastric ulcerations, gastroesophageal reflux, vomiting, diarrhea, nutritional deficiencies, and others.<sup>8,9</sup> These systemic changes, directly or indirectly, result in oral manifestations like dental caries,<sup>10</sup> dental erosion,<sup>11</sup> dental wear,<sup>12</sup> periodontitis,<sup>12,13</sup> mucosal alterations,<sup>14</sup> sialometric changes,<sup>12,15</sup> sialochemical changes,<sup>13,16</sup> and taste alterations.<sup>17,18</sup>

Gastrointestinal (GI) microbiota has been shown to affect the gut–brain axis by their involvement in inflammatory and metabolic responses.<sup>19,20</sup> Studies have reported that there is a change in GI microbiota in patients undergoing BS.<sup>21,22</sup> This change in microbiota, along with anatomic rearrangement and alteration in GI hormone levels, leads to surgery-mediated weight loss.<sup>23,24</sup> The oral cavity, being an integral part of the alimentary tract, is also reported to have altered microbiota in patients undergoing BS.<sup>13,15,16,25–28</sup> These oral microbial changes can alter the oral environment which along with other factors (changes in salivary flow<sup>12,15</sup> and salivary composition<sup>13,16</sup>) can increase the risk of oral diseases.<sup>29</sup>

As per our knowledge, to date, there is no systematic review that assesses the change in oral microbiota after BS. The findings are potentially vital as these may guide dentists in preventing damage to the oral cavity and can help medical specialists in relating them with other systematic changes commonly seen in patients after BS. The study aims to systematically review the available literature to evaluate the changes in oral microbiota in patients after BS and to correlate these alterations in microorganisms with common oral manifestations. The hypothesis framed is that there is no change in oral microbiota in patients after BS.

# Methods

Guidelines given by the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) were used in framework designing, application, and reporting of the current systematic review.<sup>30</sup> The protocol was registered with the International Prospective Register of Systematic reviews and was assigned the following identification code: PROS-PERO CRD42021267677.

# **Selection Criteria**

Inclusion and exclusion criteria are listed in **-Table 1**.

#### **Exposure and Outcome**

The exposure of interest for the current study was any form of BS, irrespective of the method (type of surgery) or time (duration after the surgery). The outcome was the change in oral microbiota after BS. The focused PICO/PECO (participant, intervention/exposure, comparison, and outcome) question was: "Is there any change in oral microbiota (O) of patients (P) who underwent BS (I) when compared with non-BS groups (C)?"

## Search Strategy, Study Selection, and Data Extraction

Electronic databases (PubMed/Medline, PubMed Central, Web of Science, and Cochrane library) were systematically searched by two independent reviewers (S.J. and A.A.) for articles published from 1987 to January 30, 2022. Different groups of Medical Subject Heading (MeSH) terms and supplementary non-MeSH terms were used. Details of search strings and Boolean operators are mentioned in **-Table 2**. Duplicate articles were removed, and there was no discrepancy in the two lists of articles. H.A. and S.J. analyzed the titles and abstracts of all the articles based on predefined inclusion and exclusion criteria. If relevant information could not be obtained, the full text of the article was reviewed. A Manual search was conducted by searching Google, *clinical*trials.gov, and references of shortlisted articles to identify relevant articles. The selected articles were cross-checked by A.A. Full texts of shortlisted articles were reviewed by S.J. and A.A., and based on the predetermined exclusion and

inclusion criteria, appropriate studies were selected. Any disagreements or differences in opinions were discussed with another reviewer (H.A.), and a consensus was reached.

Relevant data, extracted from the final articles, were tabulated in a self-designed table (**-Table 3**). The data extracted were as follows: first author's name, year of publication, the country where the study was conducted, study type (*in vitro* or *in vivo*), objects, the objective of the study, sample size (number of patients), gender, mean age, mean BMI of participants (before and after surgery), presence of comorbidities, oral diagnosis/findings, type of BS, microbiota investigation technique, location of specimen collection, time of specimen collection, change in levels of the microbiome, reported oral changes after BS, correlation of altered species with oral and general manifestations, and authors suggestions/conclusions.

## **Quality Assessment of Included Studies**

The quality of included articles was assessed using the quality assessment tools of the National Heart, Lung, and Blood Institute of the National Institutes of Health (NIH) for quality assessment of the Observational Cohort and Cross-Sectional Studies and Controlled Intervention Studies.<sup>31</sup>

The criteria for assessment are as follows: Q1., "Was the research question or objective in this paper clearly stated?"; Q2., "Was the study population clearly specified and defined?"; Q3., "Was the participation rate of eligible persons at least 50%?"; Q4., "Were all the patients selected or recruited from the same or similar populations (including the same time period)? Were inclusion and exclusion criteria for being in the study prespecified and applied uniformly to all participants?"; Q5., "Was a sample size justification, power description, or variance and effect estimates provided?"; Q6., "For the analyses in this paper, were the exposure(s) of interest measured prior to the outcome(s) being measured?"; Q7., "Was the timeframe sufficient so that one could reasonably expect to see an association between exposure and outcome if it existed?"; "Q8: For exposures that can vary in amount or level, did the study examine different levels of the exposure as related to the outcome (e.g., categories of exposure, or exposure measured as continuous variable)?"; Q9., "Were the exposure measures (independent variables) clearly defined, valid, reliable, and implemented consistently across all study participants?"; Q10., "Was the exposure(s) assessed more than once over time?"; Q11., "Were the outcome measures (dependent variables) clearly defined,

valid, reliable, and implemented consistently across all study participants?"; Q12., "Were the outcome assessors blinded to the exposure status of participants?"; Q13., "Was loss to follow-up after baseline 20% or less?"; and Q14., "Were key potential confounding variables measured and adjusted statistically for their impact on the relationship between exposure(s) and outcome(s)?"

## Results

#### Identification and Screening

The initial electronic database search leads to 2,030 titles (**-Table 2**). A total of 47 titles were found to be duplicated and were removed. Titles and abstracts of 1,983 articles were screened to exclude irrelevant articles (based on inclusion and exclusion criteria). Articles with conflicts were discussed to resolve the disagreements. Kappa score (Cohen's kappa coefficient; k = 0.922) indicates a near-perfect agreement between the two reviewers. The full text of the leftover titles was assessed to choose the suitable studies, and, finally, nine articles were shortlisted. A manual search of references for these articles was performed, but no more relevant articles were found. Out of nine selected articles, one was the postoperative microbiota data<sup>32</sup> collected from patients where the preoperative microbiota data were published separately,<sup>28</sup> whereas another study was excluded because it discussed oral microbiota after BS without comparing these changes with preoperative microbiota.<sup>33</sup> Thus finally, seven studies (reported in eight articles) were incorporated into this review. **Fig. 1** illustrates the search outcomes.

## **Quality Assessment of Included Studies**

A total of seven studies were included in this review. The quality of one study was rated as  $good^{13}$  and six studies were rated as fair<sup>15,16,25–28,32</sup> with a risk of bias due to the absence of blinding. Results of the NIH quality assessment scale are displayed in **-Table 4**.

## Characteristics of Included Studies

All the included studies (n = 7) evaluated the effect of BS on oral microbiota in humans. Included studies were published during the last 6 to 7 years (2015–2021; **- Table 3**). Three out of seven studies were conducted in Brazil,<sup>13,15,25</sup> and one each was conducted in Poland,<sup>28,32</sup> the Czech Republic,<sup>26</sup> Hungary,<sup>27</sup> and the United States.<sup>16</sup> Sample size researched and varied in these studies from  $n = 27^{15}$  to n = 154.<sup>25</sup> The

cumulative number of female participants was higher, and they contributed to 72.9% (290) of the cumulative sample size (398), whereas male participants contributed only 27.1% (108). The mean age of participants ranged from 33.9<sup>27</sup> to 48<sup>26</sup> years, with variation in each study. Four out of seven studies reported the presence of comorbidities in the selected participants (DM, hypertension, and others)<sup>15,16,26,28,33</sup>; in one study, none of the participants had comorbidities,<sup>26</sup> whereas two studies did not disclose these details.<sup>13,25</sup> With regard to relevant oral findings, two studies reported the presence of periodontitis in sample groups,<sup>13,25</sup> two studies mentioned that there was no periodontitis<sup>16,27</sup>; in one study, participants were wearing removable dental prosthesis and had dental caries,<sup>15</sup> whereas two studies did not disclose any of these details.<sup>26,28,32</sup> There was a difference in the type of BS used in the selected studies. RYGB<sup>13,15,16,25</sup> was performed in four out of seven studies, in one study, SG was the choice of the surgical technique,<sup>28</sup> four different types of BS procedures were performed in one study on the selected population,<sup>26</sup> whereas one study did not give details about the type of weight loss surgery.<sup>27</sup> The mean BMI of participants in included studies varied from 51.72<sup>15</sup> to 44.99 kg/m<sup>225</sup> in the pre-BS group/baseline group to 48.4<sup>28,32</sup> to 26.53 kg/m<sup>225</sup> in post-BS group.

Four out of seven studies compared the change in oral microbiota in the same selected participants before and after BS, <sup>13,15,16,26</sup> whereas three studies<sup>25,27,28,32</sup> compared this change in BS patients with those who have not undergone BS. For qualitative and quantitative analysis of the microbiota,

gingival crevicular fluid (GCF) was the source of specimen in two studies, <sup>13,27</sup> stimulated saliva in two, <sup>15,16</sup> unstimulated saliva in one,<sup>26</sup> and oral swabs only were collected in one study.<sup>28,32</sup> One study collected specimens from both unstimulated saliva and the dorsum of the tongue.<sup>25</sup>

Out of the total of seven studies, three used the quantitative polymerase chain reaction (qPCR) technique for relative DNA quantification of specific microbial targets, <sup>13,16,25</sup> one expressed microbiological counts as colony-forming units per milliliter (CFU/mL saliva) on selective culture media,<sup>15</sup> one used matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-TOF MS) and MALDI Biotyper for identification,<sup>27</sup> whereas two studies used 16S rRNA gene sequence analysis technique.<sup>26,28,32</sup> There are differences in the follow-up between the included studies. Follow-up varied from 1 day<sup>26</sup> to more than 24 months.<sup>25</sup>

## **Results of the Individual Studies**

All seven studies investigated the changes in oral microbiota after BS. These changes were reported as early as 1 day after BS<sup>26</sup> and continued up to 2 years of follow-up.<sup>25</sup> The type of BS was not differentially associated with bacterial diversity or specific changes in the oral microbiota; however, each study reported a marked increase or decrease in certain species after BS. The reported trend of changes in oral microbiota was highly heterogeneous between individuals within each study. Trends in changes in oral microbiota between studies were heterogenous, primarily because only two of the studies<sup>26,28,32</sup> used similar approaches in identifying, and quantitating the oral microbiota. Details of changes in microbiota are described in **~Table 3**.

*Changes in salivary microbiota*: two studies reported a significant increase in firmicutes (mutans streptococci<sup>15</sup> and *Veillonella atypica*<sup>26</sup>), one each reported an increase in sac fungi (*Candida albicans*<sup>15</sup>), bacteroidetes (*Porphyromonas gingivalis* and *Tannerella forsythia*<sup>25</sup>), spirochaetes (*Treponema denticola*<sup>25</sup>), and *Bifidobacteria*<sup>16</sup> species. Three studies reported a significant decrease in firmicutes (*Lactobacillus spp*,<sup>15</sup> *Granulicatella elegans*,<sup>26</sup> and *Parvimonas micra*,<sup>25</sup> one each reported decrease in bacteroidetes species (*Porphyromonas pasteri* and *Prevotella nanceiensis*)<sup>26</sup> and proteobacteria (*Helicobacter pylori*<sup>25</sup>).

*Changes in GCF microbiota:* Sales-Peres et al<sup>13</sup> reported a significant increase in bacteroidetes species (*P. gingivalis* and *T. forsythia*) and a significant decrease in spirochaetes (*T. denticola*) and bacteroidetes species (*Prevotella intermedia*). At the same time, Balogh et al<sup>27</sup> reported a marked increase in firmicutes (*Streptococcus*) and sac fungi (albicans and nonalbicans *Candida*) and a significant decrease in firmicutes (*Granulicatella*), actinobacteria (*Actinomyces*), and fusobacteria species (*Fusobacterium*). Changes in oral scrapings microbiota: increase in bacteroidetes,<sup>25,28,32</sup> proteobacteria,<sup>28,32</sup> actinobacteria,<sup>28,32</sup> and spriocheates<sup>25</sup> was reported in scrapings collected from the oral cavity.

# Discussion

In the current review of literature analyses, the available studies were analyzed to evaluate the changes in oral micro-

European Journal of Dentistry Vol. 17 No. 3/2023 © 2022. The Author(s).

biota in patients after BS and attempted to correlate these alterations in the number and quality of microorganisms, with oral manifestations. To the best of our knowledge, to date, there is no systematic review that assesses the change in oral microbiota after BS. The findings based on the seven selected studies improve our knowledge about the changes in oral microbiota post-BS which may aid in the effective management of changes observed post-BS. The findings support that oral microbiota is altered after BS but this variation varies with the individuals. Thus the hypothesis framed can be rejected.

Oral microbiota consists of various microbial species which colonizes in different areas of the oral cavity. The characteristics of each area determine the configuration of microbiota.<sup>34</sup> There is a critical balance between these microorganisms and the host. In the presence of systemic diseases and /or if oral hygiene is not adequately maintained, this equilibrium gets disturbed, and the quality and quantity of microbiota get altered which may manifest as oral diseases like periodontitis, caries, gingivitis, oral mucosal changes, and others. The bacterial taxa reported to be associated with caries by culture and molecular studies include Streptococcus, Lactobacillus, Actinomyces, phylotypes of Bifidobacterium, Propionibacterium, and Atopobium.<sup>34-38</sup> In contrast, taxa reported to be associated with periodontal disease include P. gingivalis, T. forsythia, T. denticola, Aggregatibacter actinomycetemcomitans, Fusobacterium nucleatum, Filifactor alocis, and P. intermedia.<sup>34,38–40</sup>

Obesity is a complex state which involves excessive fat accumulation that can have a negative effect on the overall health of an individual. Vgontzas et al<sup>41</sup> reported that proinflammatory cytokines, which are secreted by fat tissues, are directly proportional to BMI and visceral obesity. This systemic inflammation alters the oral microbiota in obese individuals, which are found to have higher levels of phylum bacteroidetes (T. forsythia and P. gingivalis),<sup>42,43</sup> phylum spirochaetes (T. denticola),<sup>43</sup> phylum firmicutes (Granulicatella adiacens and Streptococcus oligofermentans), phylum actinobacteria (actinomyces), phylum proteobacteria (Aggregatibacter) as compared with nonobese individuals.<sup>44</sup> In addition to this, comorbidities associated with obesity like type-2 DM, hypertension, hyperlipidemia, and others, also alter the oral microbiota.<sup>16,45</sup> BS is an effective treatment modality to manage morbidly obese patients and their related comorbidities in the long term.<sup>4</sup> Studies have reported a change in oral microbiota<sup>13,15,16,25-28,32</sup> in patients who have undergone BS procedures. These alterations can be associated with the site of the oral cavity. One of the prerequisites regarding microbiota analysis and comparison between groups is the absence of any relevant disease before intervention, so that observed alteration can be attributed to intervention.<sup>46</sup> In the current review, three studies reported the presence of oral disease preoperatively<sup>13,15,25</sup> and two studies did not disclose any of these details,<sup>26,28,32</sup> Five out of seven studies included antibiotic administration in exclusion criteria. One study did not include it.<sup>26</sup> In another study,<sup>16</sup> the exclusion criteria was those patients who have received antibiotics within the

previous 6 months, but during methodology, the authors mentioned administering a single dose of antibiotics to patients. Studies reported that the use of antibiotics can alter the composition of oral microflora<sup>47,48</sup> which can return back to normal after 14 days of antibiotic administration.<sup>49</sup>

When changes in salivary microbiota after BS were considered, Hashizume et al<sup>15</sup> reported an increase in Streptococcus mutans and Candida albicans and a decrease in Lactobacillus spp. This Increase in C. albicans in their study can be related to the inclusion of patients with comorbidities wearing removable dentures. Pataro et al<sup>25</sup> reported higher oral and lower stomach bacteria frequency in the BS group. They reported a nonsignificant decrease in H. pylori and an increase in the frequency of red complex species (P. gingivalis, T. forsythia, and T. denticola) in the bariatric group with a much higher number in patients having periodontitis before BS. Their results were in accordance with Jaiswal et al,<sup>50</sup> who reported no improvement in pocket depth and clinical attachment level after 6 months of BS. Džunková et al<sup>26</sup> reported a significant increase in V. atypica and a significant decrease in P. pasteri. They concluded that GI microbiota is affected directly by BS, whereas salivary microbiota is altered indirectly. Shillitoe et al<sup>16</sup> reported a 10-fold increase in Bifidobacteria species. They reported simultaneous changes in oral and lower GI microbiota which could be due to the correction of the systemic mucosal immune defect after BS and the direct influence of oral microbiota which is continuously swallowed.<sup>51</sup>

Concerning changes in GCF microbiota, Sales-Peres et al<sup>13</sup> reported a significant increase in P. gingivalis and T. forsythia and a significant decrease in T. denticola and P. intermedia. They reported worsened periodontal conditions 6 months after BS and slight improvement after 12 months of followup. Despite reduction in the body's inflammatory response, increased periodontal destruction was related to being due to indirect damage mediated by the immunoinflammatory response. They proposed that these changes could be due to frequent eating, osteoporosis,<sup>52</sup> and nutritional deficiencies which are common after BS. Balogh et al<sup>27</sup> reported a marked increase in germ count of streptococcus, albicans, and nonalbicans Candida and a significant decrease in Granulicatella, Actinomyces, and Fusobacterium. An increase in the proportion of patients affected by Prevotella sp. was also reported. The non-albicans species (C. dubliniensis, C. kefyr, and C. lusitaniae) found were similar to those isolated from the oral cavity of immunosuppressed patients. They concluded that despite changes in oral microbiota after BS, patients are unlikely to develop periodontitis if they have uninflamed periodontal conditions and good oral hygiene maintenance preoperatively.

Concerning changes in oral scrapings microbiota, Stefura et al<sup>28,32</sup> reported more proteobacteria species preoperatively, in the patients who have positive weight loss outcome (% expected weight loss [EWL] >50%), when compared with the patients who have negative weight loss outcome (% EWL < 50%), in which actinobacteria species is higher preoperatively. They reported an increase in bacteroidetes,

proteobacteria, and actinobacteria species postoperatively. Type of BS and patient's age were important factors in determining the amount of weight loss.

All the included studies had indicated a change in quality and quality of oral microbiota after BS but had dissimilar results when type and number of species were considered. Most of the studies had a common consensus that these changes in oral microbiota are not directly related to BS but could be due to indirect reasons. These reasons could be increased frequency of meals (sucrose),<sup>13,15,26</sup> underreporting of food intake by patient,<sup>33</sup> change in food consistency,<sup>15</sup> change in nutritional composition of food,<sup>33</sup> nutritional deficiencies,<sup>13</sup> altered oral pH due to frequent episodes of gastrooesophageal reflux,<sup>26</sup> use of proton pump inhibitors,<sup>53</sup> change in gut-brain axis regulation,<sup>26</sup> alterations in taste perception,<sup>26,54</sup> presence of systemic diseases/comorbidities/immunological factors,<sup>15</sup> presence of dentures in mouth,<sup>15</sup> oral health status before BS,<sup>27</sup> dental hygiene maintenance,<sup>27</sup> and individual-specific resident bacteria.<sup>26</sup>

These changes in oral microbiota can be correlated with oral and general manifestations to some extent. Altered species which have been reported to have a positive correlation with periodontitis include P. gingivalis, T. forsythia, T. denticola, P. intermedia, phyla bacteroidetes, Prevotella salivae, A. actinomycetemcomitans, P. micra, and C. rectus <sup>25,55-61</sup>. Whereas Neisseria and Bifidobacteria have a negative correlation with periodontitis.<sup>62,63</sup> S. Mutans, phylum actinobacteria, and V. atypica have a positive correlation with dental caries.<sup>64</sup> Whereas, Megasphaera micronuciformis and C. albicans, to some extent, have a negative correlation with caries.<sup>64,65</sup> C. albicans and nonalbicans Candida species have a positive correlation with immunosuppression, <sup>66–68</sup> H. *pylori* and phyla proteobacteria<sup>67</sup> have a positive correlation with gastritis, and *P. gingivalis* has been positively related to cardiovascular diseases.66,67

Knowledge of changes in oral microbiota and their relation to GI microbiota is very important. The oral cavity can act as an extra gastric pool for many microorganisms. These oral microorganisms can influence GI microbiota and other vital organs of the body directly or indirectly, causing various systemic complications.<sup>69–74</sup> Studies have reported three pathways for oral-gut allocation of microbiota<sup>75,76</sup> as follows: (1) direct invasion of the intestinal tract through the esophagus by oral microbiota; (2) through the blood cycling route, pathogenic oral microorganisms, which cause periodontitis, can enter the systemic circulation through the periodontal blood and may act on the whole body, and (3) low-grade inflammatory state caused by the metabolites of oral microbiota that enter the bloodstream and the systemic circulation. Also, it is easier/convenient to obtain oral specimens as compared with faecal specimens in long-term follow-up cases to evaluate the changes in the microbiota.

A dentist can play a vital role in monitoring the oral cavity of patients before and during follow-up visits after BS. It is evitable that at all stages, good oral health should be maintained for these patients to improve their chewing efficiency to keep pathogenic species under control and to reduce systemic complications due to bacteremia. Further longterm studies focusing on monitoring oral microfloral changes and identifying optimal oral microfloral composition after BS may help in better management of these patients.

The outcomes from the current study are also dependent on the different duration of follow-up and different approaches used by the selected articles. The follow-up period varied from 1 day<sup>26</sup> to 2 years,<sup>25</sup> and the location of oral specimen collection was also varied. There was a large variation in sample size and most of the studies had a higher number of female patients.<sup>15,16,25-28,32</sup> Thus generalization of outcomes was difficult. Also, there was no consistency in the study groups. Due to these limitations, meta-analysis was not feasible. The detailed study selection approach followed is the key point of this review. All studies related to BS and changes in oral microbiota were analyzed, thus making sure that no relevant study is missed.

# Conclusion

The outcomes of this systematic review indicate that considerable changes take place in oral microbiota after BS which can be correlated with common oral manifestations. These changes are mainly due to the indirect effect of BS and may vary with the individuals. Due to variations in the included studies, it is difficult to proclaim any persistent pattern of oral microbiota found after BS. Further long-term investigations are required to get a better picture of the altered microbiota.
