

COVID-19-Associated Acute Disseminated Encephalomyelitis: A Systematic Review

Abstract

Objective: The objective of this study was to provide an overview of acute disseminating encephalomyelitis, a potential and serious complication of COVID-19. **Methods:** Three primary databases were used, PubMed, LitCovid, and WHO. The final review articles reported acute disseminated encephalomyelitis (ADEM) in COVID-19-positive patients and were full-text, peer-reviewed articles. Articles which did not have patient data such as *in vitro* studies and articles with unclear inference were excluded. **Results:** Out of 21 cases of ADEM, the diagnosis of severe acute respiratory syndrome-coronavirus 2 was confirmed in 18 and suspected in 3. Among the neurological symptoms, altered consciousness was most common (7/21), followed by anosmia (3), paraplegia (3/21), brain stem involvement (3/21), sphincter involvement (2/21), and quadriplegia (1/21). Raised inflammatory markers were most commonly seen in 9/17. Central nervous system imaging was abnormal in 19 cases and unavailable in 2 cases. Fifteen patients were treated with corticosteroids, 11 patients received intravenous immunoglobulin, while 3 patients received convalescent plasma. Two patients needed surgical intervention. Complications included seizures (1), acute kidney injury and septicemic shock (1), raised intracranial pressure (1), and supraventricular tachycardia secondary to hydroxychloroquine (1). One patient recovered completely and one had good recovery with mild deficits. Thirteen patients had incomplete recovery with residual neurological deficit while three patients died as the consequence of the disease. **Conclusion:** The physicians and neurosurgeons should be diligent while treating the COVID-19 patients with neurological manifestations and include ADEM as a differential diagnosis and stress on early diagnosis and treatment to reduce mortality and achieve satisfactory clinical outcome.

Keywords: Acute disseminating encephalomyelitis, COVID-19, neurological complications, neurological manifestations

Introduction

The coronavirus pandemic began in December 2019 with Wuhan, China, being the epicenter.^[1] As per the latest reports on August 8, 2020, there have been 20,806,961 cases worldwide with 747,258 deaths due to COVID-19.^[2]

Many reports have indicated extrapulmonary involvement of severe acute respiratory syndrome-coronavirus 2 (SARS-CoV-2).^[3-7] The common neurological manifestations include headache, anosmia, hypogeusia, and altered consciousness while seizures, encephalitis, meningitis, encephalopathy, demyelination, and stroke are potential serious complications.^[8,9]

Acute disseminated encephalomyelitis (ADEM), an acute inflammatory

autoimmune demyelinating disease of the central nervous system (CNS),^[9,10] is often preceded by a viral infection, but the evidences depicting its occurrence as a complication of SARS-CoV-2 are scarce.^[10,11] Our study aims to provide an overview of this potential but serious complication of COVID-19.

Methods

A systematic search was conducted for research articles on COVID-19-associated ADEM. Three primary databases were used, Pub-Med, LitCovid, and WHO. The search strategy used the keywords, corona virus, COVID-19, neurological complications, and acute disseminated encephalomyelitis, and was comprehensive with cross-checking of reference lists from

the articles retrieved. Selected articles were independently reviewed by two authors. All disagreements were resolved with discussion between the two authors and mutually agreed upon by the authors. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines were used [Figure 1].^[12] The final review articles fulfilled the following criteria:

1. Reported ADEM in COVID-19-positive patients
2. Full-text, peer-reviewed articles (case studies and case series).

Articles which did not have patient data such as *in vitro* studies and articles with unclear inference were excluded.

This study did not require ethical approval as data were obtained from already available databases and patients were not directly involved.

Risk-of-bias assessment

Risk-of-bias assessments were performed at the outcome measurement level during data collection. The National Institute of Health scale was used for case series and case report studies^[13] [Table 1].

Results

A total 135,160 articles were found from the database using the abovementioned keywords until August 8, 2020.

After de-duplication, 73,500 articles were screened and 4932 were found to be pertaining to neurological manifestations of COVID-19. Out of which, 1585 were focusing on COVID-19-associated acute disseminating encephalomyelitis. After the initial screening, articles were reviewed, out of which 680 articles matched the inclusion criteria. These articles were then screened in the second review. Before the qualitative synthesis, 668 articles were removed from the listed articles as they did not contribute to the manuscript's objective. The final analysis contained 14 articles [Figure 1]. Two independent reviewers reviewed all articles. Out of the 14 articles, 11 articles are case reports, 1 article is a case series, 1 is a retrospective cohort study, and 1 is a webpage/news article.

Novi *et al.*,^[14] Parsons *et al.*,^[15] Zoghi *et al.*,^[16] Zanin *et al.*,^[17] and Zhang *et al.*^[18] reported cases of ADEM following COVID-19 while Abdi *et al.*^[19] reported the ADEM case

without prominent clinical pulmonary symptoms. The case reported by Utukuri *et al.*^[20] had no respiratory symptoms of COVID-19 while Reichard *et al.*^[21] described the case where ADEM was confirmed by autopsy. Sharma^[22] reported India's first COVID 19-associated ADEM. McCuddy *et al.*^[23] presented a case series of three cases of COVID-19-associated ADEM while Paterson *et al.*^[24] described the retrospective cohort study of neurological manifestations of COVID-19 including ADEM. Yong *et al.*^[25] reported the cases of acute hemorrhagic leukoencephalitis while Poyiadji *et al.*^[26] described acute hemorrhagic necrotizing encephalopathy [Table 2].

Demographic data

From the 21 total cases, 10 (47%) were male patients and 11 (53%) were female patients. Female:Male ratio is calculated to be 0.9:1. The age range of the patients

Table 2: Study characteristics

First author	Type of the study	Number of patients	Age/sex	Comorbidities	Duration of COVID	Symptoms of COVID	SARS-CoV-2 diagnosis	Neurological presentation	CSF routine
Novi <i>et al.</i>	Case report	1	64/female	Hypertension and monoclonal gammopathy	25 days	Anosmia and ageusia	Serum IgG positive, negative nasopharyngeal swab	Mild behavioral abnormalities (irritability), headache, bilateral relative afferent pupillary defect, ageusia and anosmia, severe visual loss, right abdominal sensory level, and left-sided lower-limb hyperreflexia with the Babinski sign	Total cell count: 22 cells/mm ³ , Protein 45.2 mg/dL
Abdi <i>et al.</i>	Letter to editor/case report	1	58/male		No prior pulmonary/constitutional symptoms	-	Positive nasopharyngeal swab	Decreased level of consciousness, LL weakness, gait disturbance	Normal
Utukuri <i>et al.</i>	Letter to editor/case report	1	44/male	Nil	No prior respiratory symptoms	-	Positive nasopharyngeal swab	Urinary retention, bilateral lower-limb weakness and loss of sensations, inability to walk, bilateral UL ataxia.	Normal

was 21–71 years with a mean age of 51.36 years. Diabetes mellitus was the most common comorbidity seen in four patients, followed by hypertension seen in three patients. Other comorbidities were ischemic heart disease (1) and dyslipidemia (1). One patient had a past history of anterior communicating artery aneurysm clipping 20 years ago. Four patients had no prior illnesses, and details of 10/21 patients were not mentioned in the studies.

History of COVID-19

Out of 21 cases of ADEM, the diagnosis of SARS-CoV-2 was confirmed in 18 and suspected in 3. Out of 18 confirmed cases, 14 patients had positive oropharyngeal swab SARS-CoV-2 reverse transcriptase–polymerase chain reaction (RT-PCR), 1 patient had positive serum SARS-CoV-2 RT-PCR, 1 patient had positive cerebrospinal fluid (CSF) SARS-CoV-2 RT-PCR, and 2 patients tested positive for serum SARS-CoV-2-immunoglobulin G (IgG) with a negative oropharyngeal swab.

Only 15 patients presented with prior symptoms of SARS-CoV-2 infection. One patient contracted the infection in postoperative period while they were unspecified in three patients. Fever was the most common presenting symptom (9), followed by cough (6), fatigue, and myalgia (3).

Symptoms/clinical presentation

The duration of COVID-19 symptoms ranged from 3 days to 25 days before onset of neurological symptoms. Among the neurological symptoms, altered consciousness was most common (7), followed by anosmia (3), paraplegia (3), brain stem involvement (3), sphincter involvement (2), and quadriplegia (1). Only two patients directly presented with neurological symptoms.

Laboratory investigations

Blood investigations and CSF analysis were done in 17 patients. Raised inflammatory markers were most commonly seen in nine (ferritin raised in four, C-reactive protein in five, and D-dimer in five), and lymphopenia was seen in four patients.

CSF analysis was not reported in four patients. The reasons for the same were traumatic tap (1), raised intracranial pressure (ICP) (1), pandemic reason (1), and unknown reason (1).

Eight patients had normal CSF analysis on routine microscopy. Out of nine abnormal reports, increased CSF protein level was the most commonly reported abnormality in six, followed by lymphocytic pleocytosis in four patients. Meningitis was ruled out by negative CSF bacterial cultures in 5 and viral panel in 15 out of 17 patients. One CSF sample grew *Staphylococcus capitis* which was probably contaminated.

Although there was neurological involvement in all cases, CSF SARS-CoV-2 PCR was positive only in 1 patient out

of 13 who were tested. One patient had brain tissue CoV-2 PCR negative on autopsy.

CSF autoimmune analysis was done in 17 patients. Only one patient had a CSF-IgG ratio of 1.35, one patient had four oligoclonal bands (OCBs), while one patient had mirror pattern of serum and CSF IgG. Antibodies for myelin oligodendrocyte glycoprotein (MOG) and aquaporin-4 were negative in nine patients.

Radiological investigations

CNS imaging was abnormal in 19 patients and unavailable in 2 patients. Diffuse white matter changes, occasionally involving the deep gray matter, were the most common finding. Out of 21 cases of ADEM spectrum, 13 were ADEM, 7 were AHM (acute hemorrhagic encephalomyelitis [AHM]), while 1 was acute necrotizing hemorrhagic leukoencephalopathy (ANHLE).

Treatment

Fifteen patients were treated with corticosteroids, 11 patients received IVIg, while 3 patients received convalescent plasma. Two patients needed surgical intervention: one patient underwent decompressive craniectomy (ADEM with hemorrhage) and the other one underwent external ventricular drainage.

Complications

Complications included seizures (1), acute kidney injury (AKI) and septicemic shock (1), raised ICP (1), and supraventricular tachycardia (SVT) secondary to hydroxychloroquine (HCQ) (1).

Outcome

One patient recovered completely and one had good recovery with mild deficits. Thirteen patients had incomplete recovery while three patients died as the consequence of the disease. The cause of death in these three patients was status epilepticus, septicemic shock with multiorgan failure and severe necrotizing encephalitis respectively.

Discussion

The clinical spectrum of COVID-19 is commonly represented by the respiratory system, but it also has myriad extrapulmonary manifestations, and neurological involvement is not unknown. Similar to other coronaviruses, SARS-CoV-2 also has neurotropic potential and the neurological manifestations of SARS-CoV-2 include anosmia, headache, seizures, cerebrovascular accidents, meningitis, encephalitis, ADEM, Guillain–Barre syndrome, and cerebral venous thrombosis.^[27]

SARS-CoV-2 may directly invade the CNS, or it may cause a parainfectious autoimmune disease. ADEM is one such parainfectious disease affecting the CNS. It is commonly seen in pediatric population with few cases reported in

adults. The pathogenesis of ADEM is still unclear. The most likely mechanism is autoimmunity triggered by cross-reaction of viral antigens to myelin proteins. AHEM or ANHLE are variants of ADEM which have a fulminant course.^[9,10]

Recent literature on COVID-19 suggests that it also can have neurological manifestations with mechanisms similar to other members of its family. Yeh *et al.* reported the first case of ADEM associated with coronavirus OC43 in 2003 where the virus could be isolated from the CSF.^[28] Arabi *et al.* reported a case of ADEM following a Middle East respiratory syndrome infection in 2015.^[29] The routes of spread to the CNS can be hematogenous or retrograde via the olfactory nerves. The virus then uses angiotensin-converting enzyme 2 receptors on endothelial cells to enter the brain.^[5-7,30] In an autopsy study, Paniz-Mondolfi *et al.* confirmed the presence of SARS-CoV-2 virus particles in the brain. They observed these viral particles in the endothelial cells of the frontal lobe of the brain.^[31]

We had 18 confirmed cases of SARS-CoV-2, out of which only one patient had positive CSF SARS-CoV-2 PCR.

ADEM is a diagnosis of exclusion and needs high level of suspicion. The medical fraternity is overwhelmed with the current situation of the pandemic, and rare diagnoses may not seem very obvious unless specifically considered. According to a study by Pohl *et al.* and Silvia Tenenbaum *et al.*, ADEM is characterized by prodromal symptoms, followed by acute-onset encephalopathy along with multifocal neurological deficits.^[20,21,32-34] We studied 21 patients of ADEM in SARS-CoV-2 infection and found that 71.4% (15) patients had a viral prodrome before the onset of neurological symptoms. Fever (9) was the most common presenting symptom, followed by cough (6), fatigue, and myalgia (3). These may not always be present in every case of ADEM and some patients may directly present with the neurological symptoms. Lin *et al.* studied 50 cases of ADEM and concluded that previous history of upper respiratory tract infection was seen only in 50% of the cases.^[35] In our study, Abdi *et al.*^[33] and Utukuri *et al.*^[20] described one case each where the patient directly presented with neurological symptoms while Reichard *et al.*^[21] described a case where an elderly patient contracted the infection postoperatively.

Wender *et al.*^[10] in their study mentioned that the presenting clinical features of ADEM were altered sensorium, seizures with focal neurological deficits like speech difficulty and limb weakness. Our findings were parallel to the literature and that altered sensorium was the most common neurological presentation seen in seven patients. Brain stem involvement indicates severe disease and was seen in three patients; all were elderly patients aged 48, 51, and 59 years.^[15,24,36] Other neurological symptoms in our study were anosmia, limb weakness, and sphincter involvement. Less

common symptoms were limb ataxia described by Utukuri *et al.*^[20] in one case and vision impairment described by Novi *et al.*^[14] in one case. Zhang *et al.* in their case report described a case with seventh and lower cranial nerve involvement with gaze abnormality.^[18] Gaze abnormality was also seen in another case described by McCuddy *et al.*^[23]

Blood investigations were mentioned in 17 patients. We found that the inflammatory markers were raised in 9/17 patients. It indicates pro-inflammatory state likely from the preceding infection. Four patients had lymphopenia suggestive of a viral infection. CSF analysis in suspected cases of ADEM is done to rule out infection or CNS pathologies. While CSF picture in ADEM is characteristic for its lack of abnormality, it may be abnormal in almost half of the patients.^[37-41] The abnormal CSF findings were mild lymphocytic pleocytosis and elevated proteins which were seen in 30-40% of the patients.^[32,34,42-45] In our study, 17 patients underwent CSF analysis which was normal in eight patients (47%). Out of the nine abnormal CSF analyses, raised CSF proteins were seen in six patients and lymphocytic pleocytosis was seen in four patients.

Bacterial meningitis was ruled out categorically in 5 out of 17 patients while viral panel was negative in 15 out of 17 patients. SARS-CoV-2 virus could not be isolated from the CSF samples. PCR was performed in 13 patients out of 21 and it was positive only in 1 patient reported by Novi *et al.*^[14] Paterson *et al.* reported one case of ADEM with hemorrhage who needed decompression craniectomy where they obtained brain tissue for examination. They too could not isolate the virus in the brain tissue.^[24]

Only one autopsy study by Paniz-Mondolfi *et al.* provides evidence for the presence of SARS-CoV-2 virus particles in the brain. They observed viral particles in the endothelial cells of the frontal lobe of the brain.^[31]

CSF and Autoimmune analysis is an important part of investigations in ADEM cases. OCBs are inconsistently found in CSF in patients of ADEM. They have been reported only in 10%–50% of cases.^[37-39,46] The presence of OCBs is suggestive of evolution to multiple sclerosis (MS).^[47] In our study, CSF autoimmune workup was available in 17 patients. Parsons *et al.*^[15] described one patient of ADEM who had 4^cCBs in CSF.

Mirror pattern of OCB suggests that they are found in CSF as well as the serum. It is not specific for the diagnosis of ADEM. It only indicates the same autoimmune process in the serum as well as the CSF. Novi *et al.*^[14] described another patient of ADEM with positive mirror pattern of OCB. Among the serum autoimmune studies to diagnose ADEM, high serum anti-MOG antibodies are found in almost half of the patients with ADEM, although they too are not specific to ADEM.^[10,48]

The diagnosis of ADEM is based on multifocal CNS involvement, alteration of sensorium (encephalopathy),

and brain and spine magnetic resonance imaging (MRI) consistent with demyelinating lesions. Imaging is an important pillar in the diagnosis of ADEM. The MRI findings of ADEM in the studies by Pohl *et al.*^[32] and TENEMBAUM *et al.*^[34] were multiple asymmetric bilateral hyperintensities, involving subcortical and deep white matter, grey white matter junction, deep grey nuclei, corpus callosum, brain stem, cerebellum and in one third of the cases even long segments in spinal cord. Bilateral thalamic involvement is seen in ANHLE which is a fulminant variant of ADEM. It is rapidly progressive and has high mortality.^[49]

Brain lesions may be small or large confluent. They are usually hyperintense on T2-weighted and fluid-attenuated inversion recovery sequences and at times may show minimal enhancement. We found that almost all patients had bilateral asymmetric extensive lesions involving the subcortical and deep white matter. Novi *et al.*^[14] described one patient who had optic nerve enhancement in postcontrast MRI. It occurs due to breakdown of the blood–brain barrier. We found that contrast-enhancing lesions were seen in 7 out of 13 patients of ADEM, 5 out of 7 patients of AHLE, and 1 patient of ANHLE. Contrast enhancement is thus suggestive of a severe disease as seen in AHLE and ANHLE. Four patients also had features of myelitis on imaging involving long segments.

MS is a differential diagnosis of ADEM. Although there are no absolute criteria, it is important to differentiate ADEM from MS. Characteristics Multiple Sclerosis lesions are periventricular in location, solitary, perpendicular to corpus callosum and 'black hole appearance' on T1.^[32] Gray matter involvement and absence of CSF OCB also help in ruling out MS. History is also important, and MS does not follow a viral illness or vaccine. Other differentials to consider are MOG antibody-associated disease, neuromyelitis optica spectrum disorder, Progressive multifocal leukoencephalopathy–John Cunningham virus, and sarcoidosis.^[50]

To date, there have been no randomized controlled trials and treatment of ADEM is not standardized. High-dose steroids are the first line of treatment, followed by intravenous Ig (IVIG) and plasmapheresis in nonresponders. High-dose steroids consist of intravenous methylprednisolone administered at 30 mg/kg/d (maximum 1 g/day for 5 days), followed by oral taper for 4–6 weeks that has shown to be effective in 60%–80% of the cases.^[32,34,51,52]

In our study, eight patients received combination therapy with IV methylprednisolone as well as IVIg. There was no mortality in any of these patients, and all of them showed partial recovery. Four patients received only IVIg, while other four patients received only IV methylprednisolone and two patients received convalescent plasma. Acyclovir was given in two, remdesivir in one, HCQ in two, and antibiotics in four patients. Treatment details of one

patient were unavailable. Literature shows that supportive empirical treatment with acyclovir is given in some cases of encephalitis till infective cause can be ruled out. The same, however, does not apply for empirical use of antibiotics.^[53]

We found that four patients developed complications. They were status epilepticus (1), AKI and septicemic shock (1), raised ICP with mass effect and midline shift (1), and acute hydrocephalus and SVT (1). Out of these, AKI and septicemic shock were secondary to SARS-CoV-2 infection in a case described by Reichard *et al.*^[21] They describe a 71-year-old male patient who contracted SARS-CoV-2 postoperatively and subsequently developed ADEM. His course was complicated by respiratory failure and AKI secondary to septicemic shock. He required continuous renal replacement therapy but eventually succumbed.

Abdi *et al.*^[33] describe a case of a 58-year-old male patient diagnosed as ADEM, who had status epilepticus and finally succumbed. Paterson *et al.*^[24] describe a case with AHLE who developed raised ICP and required decompressive hemicraniectomy. Another patient of AHLE developed SVT secondary to HCQ treatment which could be managed medically. The same patient had also intraventricular hemorrhage and obstructive hydrocephalus for which he needed an external ventricular drain.^[36]

ADEM has a favorable outcome in 10%–50% of patients who may show complete recovery.^[37,38,40] We observed that 14% (3) patients had good outcome at the end of treatment while 66.6% (14) patients had partial ongoing recovery including all those with AHLE, some patients may be left with residual neurological deficits or may even have a relapse. In case of a relapse, the likelihood of MS should be kept in mind.

The mortality rate of ADEM is reported as 5%–12%^[37,38] while another study reported it to be 25%.^[54] Adults have a more serious course of ADEM as compared to children. The rapidly progressive cases such as ANHLE or AHLE can be fatal. In our study, mortality was 14% (3) while the outcome of one patient remains unknown at the time of writing this article.

Our study proves to be an important evidence in the literature where data on ADEM as a rare complication of COVID-19 are scarce. However, these findings could be confirmed by larger scale studies. Another limitation of our study is inclusion of data from webpages/news report article^[22] as the official case reports of few cases were unavailable at present. This could reflect poor quality of the included study.

Conclusion

In the current situation with very few studies available focusing on this rare complication, our study proves to be an important link in the evidence and literature.

The importance of knowledge about this less known but important clinical entity cannot be understated. The physicians and neurosurgeons should be diligent while treating the COVID-19 patients with neurological manifestations and include ADEM as a differential diagnosis and stress on early diagnosis and treatment to reduce mortality and achieve satisfactory clinical outcome.
